The product layout is also known as *flow-line layout*, *production-line layout*, *assembly-line layout*, and *layout by product*. In a product layout, the machines and workstations are arranged in the sequence corresponding to the sequence of operations undergone by the product. For example, if a product undergoes milling, drilling, assembly, and packing operations in sequence, the vertical milling machines, drilling machines, assembly equipment, and packing equipment must be arranged one after the other in a line. This type of layout is mostly used by companies that manufacture a single or few items in large quantities (e.g., an automotive assembly plant). The most important advantage of this layout is reduced material handling

effort and time, minimal in-process inventory, and efficient planning and control. A major disadvantage is the relative inflexibility of the layout to changes in product mix or volume. Product mix includes the types of products that need to be produced and the volume represents the (annual) demand for the product. Therefore, this type of layout is not suitable for companies that frequently change production volume or variety.

Process Layout

The process layout is also known by other names such as *layout by process* or *jobshop layout*. In a process layout, machines and work stations are arranged on the basis of the processes they perform. For example, all milling machines are placed together in one department, all turning machines are placed together in another, and so on. A process layout is shown in Fig. 1. Each geometric shape represents a particular machine type; for example, circles represent drilling machines, squares represent milling machines, triangles represent pressing equipment, and so on. In a process layout, machines that perform the same process are grouped together in their own department.

The process layout is useful for companies that manufacture a wide variety of products or process a wide variety of jobs, in small quantities. The process layout is flexible and it allows workers to become experts in a particular process. The disadvantages of this layout are the increased material handling costs, long travel distances, high inventory, long cycle times, complexity in planning and control, and decreased productivity.

Figure 1. A process layout.

Figure 2. A GT-based or cellular manufacturing layout.

Fixed Position Layout

Fixed position layout is also referred to as *project layout*. In a fixed position layout, the product does not move from one location to another. Instead, the processes and equipment move to the product's location to perform the necessary operations. This layout is usually adopted when the manufactured or processed product is bulky and cannot be transported easily. Ship and aircraft manufacturing and dam, road, and house construction are some examples that employ this type of layout. The advantages of fixed position layout are that the likelihood of damaging the product and the cost of moving it are reduced. On the other hand, the cost of moving equipment to and from the work area is significantly high and the equipment utilization is low.

Group Technology–Based Layout

Group technology (GT) is a manufacturing philosophy in which similar parts are grouped together to maximize production efficiencies. Companies making a large

number of parts often manufacture these on a large number of machines. Managing this complex system as a whole is often difficult and inefficient. If such a large system can be divided into independent and smaller subsystems, managing all the subsystems separately is much easier and cost effective than attempting to manage the complex system as a whole [7]. In order to identify the subsystems, planners must first determine the sets of machines (machine cells) which can process corresponding families of parts (part families) in such a way that all or most of the operations required by any part in a part family are almost entirely processed by a subset of the machines in the corresponding machine cell. This type of layout is also known as *cellular* or *cellular manufacturing* layout.

A GT-based layout is illustrated in Fig. 2. The difference between a GT and process layout is that machines in a cell are not necessarily similar in their processing capabilities. The advantages of GT are reduced traffic congestion, material handling costs, WIP inventory, production lead times, and other forms of waste.

Hybrid Layout

As and when companies expand their production range and capabilities, so does machine variety. Very soon these companies find that the layout type used previously does not meet their needs entirely. Thus, they may choose to have a GT layout for the new set of machines added to the facility which already has a production-line layout. Figure 3 shows a sample hybrid layout that has characteristics of a process, GT, and product layout.

Figure 3. A hybrid layout.

Figure 4. Layout classification based on volume-variety. (Source: Adapted from [4].)

The layout type which is suitable for a facility depending on product volume-variety can be summarized as in Fig. 4.

is further developed to include budget and time for the new layout establishment.

SYSTEMATIC LAYOUT PLANNING

Systematic layout planning (SLP) is a simple, step-by-step approach in the design of facilities. Even today, it is widely used to develop layouts. It consists of four steps [8].

Step 1—Determination of the location where departments will be established. In this step, the locations of the facilities or departments are determined.

Step 2—Overall layout establishment. In this step, the flow of materials between departments, space requirement for each department, and closeness requirements of departments are determined. Constraints such as safety and budget are also considered. Up to five alternate layouts are developed in this step. Then, the best layout is chosen according to designer preferences.

Step 3—Detailed layout plan development. In this step a detailed layout including the location of each machine, their supporting stations such as inspection station, and other facilities such as restroom and locker rooms are determined.

Step 4—The selected layout installation. In this step, the selected layout

Additional information on the SLP is provided in Refs 3, 4, 9.

NEXT-GENERATION FACILITY LAYOUTS

The discussion about traditional layouts in the section titled “Facility Layout” did not focus on minimizing inventory, shortening cycle times, or increasing flexibility. The focus was primarily on factors such as minimization of (loaded) material handling trips or costs, facilitating supervision or communication between personnel, and so on. Moreover, the GT and product layouts are designed assuming that changes in product mix and volume are relatively stable over a long period, say 3–5 years.

Today’s factories face constant changes in production requirements, and the production environment is thus highly dynamic. Existing layouts are not fully capable of meeting such changes or operating efficiently in such environments. Benjaafar *et al.* [10] point out the need for a new generation of facility layouts that are more flexible, modular, and easy to reconfigure. Other researchers such as Askin *et al.* [11], Benjaafar and Sheikhzadeh [12], Irani and Huang [13], Kochhar and Heragu [14], Montreuil [15], National Research Council [16], and Yang and Peters [17] have also pointed out the need for alternate types of next-generation factory layouts.

The metric for evaluating layouts has also changed in today's factories. The "robustness" of a layout over long time periods (during which there is a significant evolution relative to the product mix and volume) is of importance. Layouts that can be configured and reconfigured as frequently as necessary to meet the changing product mix and volume are also of importance. Modern layouts must lower inventories, decrease production lead times, and offer greater flexibility for product customization, in addition to minimizing the traditional measures such as minimizing loaded material handling trips.

Robust layouts are those that remain relatively efficient over relatively long periods from a material-handling standpoint even though the product mix and volume may have shifted dramatically from one planning period to the next. Robustness is typically achieved by duplicating key processes or machines at strategic locations within the production facility.

Reconfigurable layouts are those that can be changed relatively easily each time there is a moderate or heavy shift in product mix and volume. The assumption is that the costs of physically changing the layout from one configuration to another is relatively less expensive and time consuming and thus the benefits of a new layout for a given product mix and volume can be more fully realized [1,18]. Of course, an implicit assumption here is that the production processes are relatively

light-weight, a trend that is being seen in many process industries.

To develop reconfigurable manufacturing systems (RMS) with new methodologies and equipment, the Engineering Research Center for Reconfigurable Manufacturing Systems (ERC/RMS) at the University of Michigan (<http://erc.engin.umich.edu/>) focuses on building machines that can be quickly adjusted for changes in product mix or volumes. For example, machines can be quickly upgraded by adding spindles, axes, tool magazines, or controllers [19] so that facilities may use one machine for much of the processing without incurring any material handling movement or cost. Because a machine can be configured for different mixes and volumes easily, changes in production requirements will not affect the layout significantly.

Holographic layout is an alternative to process layout for systems operating in highly volatile environments. In this type of layout, subdepartments or machines are distributed throughout the shop floor. Duplication of departments or machines throughout the factory may also allow the facility to respond to future fluctuations quickly (see Fig. 5). Because the machines are dispersed throughout the building, it is possible to reduce material handling costs somewhat using holographic layouts. To design this layout, the planner should decide how to disaggregate and duplicate the subdepartments or machines throughout plant [13,20].

Figure 5. Holographic layout. (a) Partially distributed layout. (b) Entirely distributed layout. (Source: Adapted from [10].)

Figure 6. Facility layout problem reference model. (Source: [1].)

Fractal layouts can be helpful to a company that handles products requiring short runs or products having short life cycles. Temporary cells are formed by joining sub-departments dedicated to a particular product line or job order. This cell can be switched with a new one when a product is phased out or when a customer order is completed and a new one arrives. Drolet [21] studied such virtual cells. Lahmar and Benjaafar [22] found that distributed configurations can be effective in handling production growth and contraction.

LAYOUT DESIGN AND ANALYSIS²

To put a layout problem into context, the entities and activities relevant to the layout problem can be organized into a layered model as shown in Fig. 6. The reference model has three physical layers: product mix, machine types, and locations on the shop floor. Each available machine belongs to a machine type. The number of locations on the shop floor is equal to the total number of machines. The two logical layers of the

reference model denote the design activities involved. The process planning problem maps each product to a sequence of machine types. Its output (product routings) includes other production data such as processing time, setup time, and tooling information. The layout problem is to find a one-to-one mapping from machines on the machine types layer to locations on the shop floor. The third logical layer (not shown) pertains to the scheduling problem. It finalizes the machine types in a product routing to specific machines on specific shop floor locations, and coordinates the timing, sequencing, and prioritizing of all work orders assigned to one machine.

The solution of the layout problem is determined by entities and activities in other layers of the reference model. Let us define the collection of these entities and activities (i.e., product mix, product routings, machines, and locations on shop floor) as the context of a layout problem. As long as the context is fixed, theoretically speaking, there exists an optimum layout for this context. By definition, the facility layout problem is a simple assignment of n machines to n locations on the shop floor. What makes the facility layout problem difficult to solve is the large combinatorial search space, especially when n is large (possibly $n!$ feasible solutions if there are no special restrictions on the locations

²Some of the material in this section has been reproduced from [1] with permission.

of specific machines or relative location of a subset of machines) and the construction of a score function that incorporates various business considerations to evaluate the goodness of a layout.

Koopmans and Beckman [2] first presented the QAP in the context of macrolevel facility location problems, but it has been extensively used to model microlevel factory layout problems. Since the 1960s, there has been a significant volume of research focused on solving the QAP, hence the layout problem, optimally. Assuming the cost to transport a unit load of material through a unit distance is known between each pair of facility locations, the objective of a QAP is to find optimal assignment of all the facilities to locations so that the overall cost of transporting material between each pair of facility locations is minimized. Ever since the QAP was adopted for the microlevel facility logistical problems, there have been numerous attempts to solve it optimally. But because the QAP is known to be NP-complete, optimal algorithms cannot solve problems with more than 15 or 20 facilities. Real-world layout problems, however, are much larger, and numerous attempts have been made to solve the QAP heuristically. Several sources including Kusiak and Heragu [23], Meller and Gau [24,25], and others have surveyed these optimal and heuristic algorithms. A major drawback of adapting the QAP for the layout problem (and hence the techniques developed to solve the QAP-based layout problem) is that the QAP assumes the locations of facilities to be known *a priori*, implicitly assuming that the facilities are of the same area and shape. Because this assumption does not reflect reality—not all facilities will have the same shape and area—Heragu [26] and others have introduced more realistic modeling representations of the layout problem and appropriate techniques to solve them.

Another important deterministic solution procedure in facility layout problem uses space-filling curves. Bozer *et al.* [27] show how to use it in facility design problem by extending a layout algorithm—CRAFT—for solution of multiple floors layout. Using ideas from drawing space-filling curves, they come

up with a more efficient exchange of two departments than is possible via two-way or three-way exchanges. Bozer *et al.* [27] define the new algorithm as MULTIPLE (MULTI-floor Plant Layout Evaluation). They illustrate how space-filling curves and flexible department areas allow MULTIPLE to increase the number of exchanges within a floor and the number of exchanges across floors without splitting departments as well as how MULTIPLE controls department shapes.

The static plant layout (SPLP) minimizes the total material handling costs by assigning departments to various locations. It is usually formulated as a QAP. However, Rosenblatt [28] studied dynamic plant layout and developed optimal procedure for this problem on the basis of dynamic programming formulation. In this study, because solving a problem with a large number of departments may be computationally prohibitive, he also recommends heuristic approaches.

All of the above-mentioned layout models and techniques treat the problem in a deterministic manner. For example, a major assumption made by traditional layout models and algorithms is that the material flows between each pair of facilities is known well into the future (say, for a period of 5 years or more) *and* that these values do not change. Current realities simply do not allow us to look at these values as being static. The dynamic nature of today's manufacturing and service activities does not allow us to predict material flows that far into the future. Often, we are fortunate if we can predict material flows for the upcoming planning period. Moreover, as pointed out by Heragu and Kochhar [29], two changes taking place in the manufacturing design and manufacturing process technologies enable us to envision layouts that can be changed relatively frequently for relatively low cost.

1. Because we are making products increasingly with light-weight composites that can be engineered to have all the desired tensile strength, and other mechanical properties, machines or material handling systems processing or transporting these composite

products need not be heavy or require elaborate foundations.

2. Noncontact manufacturing processes such as electron beam welding and laser cutting also suggest that we do not need heavy machines with elaborate foundations. In fact, Heragu and Kochhar [29] have proposed light-weight machines with wheels and mounted on tracks that can be clamped in any desired location in a grid of tracks on a factory floor permitting their movement from one location to another as frequently as production changes warrant.

As discussed in Heragu and Kochhar [29], composites are the primary choice for many discrete manufactured components. Aluminum composites, for instance, can now replace cast iron parts, and phenolics are replacing aluminum parts [30,31]. Not only are these light but they can also be engineered to have excellent mechanical properties such as hardness, heat resistance, tensile strength, and vibration absorption. The last property permits machine tool designers to design functionally equivalent but lighter tools that do not require an elaborate foundation, making them easily movable. Nonabrasive manufacturing process technology, such as laser cutting, electron beam hardening, and molecular nanotechnology, also supports machine tool designers' quest for making light-weight machining equipment [32]. Permanent magnetic chucks that facilitate quick mounting and dismounting of tools are being developed [33]. In fact, these chucks do not magnetize the cutting tool, carry their own energy source, and do not obstruct machining. Once again, these features in and of themselves support rapid equipment reconfiguration. This trend is likely to continue well into the next two decades. In fact, through a workshop and a delphi survey, the committee on Visionary Manufacturing Challenges for 2020 has identified adaptable processes and equipment and reconfiguration of manufacturing operations as two key enabling technologies that will help companies overcome two of the six grand challenges or fundamental goals to remain

productive and profitable in the year 2020 [16]. These grand challenges are to *achieve concurrency in all operations* and to *reconfigure manufacturing enterprises rapidly in response to changing needs and opportunities*.

Numerous examples where facility layouts are modified on a frequent basis, sometimes every few months, have been cited in Benjaafar *et al.* [11]. Northern Telecom, in one of its manufacturing facilities facing constant product design changes, employs conveyor-mounted work cells that can be readily relocated just before a scheduled production/assembly change [34]. A primary advantage of reconfiguring a layout when warranted by changes in product mix and volume is that material handling cost can be minimized because equipment can be reconfigured to suit the new production mix and volume. Of course, this cost must more than offset the cost of moving equipment from its current location to a new one.

Thus, given the new reality that layouts are likely to change very frequently, possibly every few months rather than years and that, at best, we only have knowledge of the production activities during the upcoming planning period, we need to develop a layout only for the next planning period. In addition, due to the short term life of a given layout and availability of production data for this time period, it is possible to consider optimizing operational performance measures such as minimizing part cycle times and WIP inventory.

Notice that it is relatively easy to get detailed data on material flows, machine setup, process and transfer batching, and others relative to the production activities in the next period as opposed to manufacturing activities for the next 5 years. Although the required data are available, it is well known that these data are not static. For example, the time to transport a load from one machine to another is a function of where the material handling device (assigned to transfer that load) is located at the time the material transfer request comes in. Even if we were to assume that the device is always at the same known location, the travel time is determined by congestion and other factors and is highly variable.

Thus, it makes sense to develop stochastic models for layout analysis. Furthermore, because many factors—deterministic as well as stochastic—have an impact on determining the suitability of a layout, we need tools that can design and analyze a layout with respect to static design criteria *and* stochastic operational performance criteria. Developing layouts on the basis of static design criteria alone is inadequate and, in some cases, could lead to undesirable consequences. For example, Benjaafar [11] has shown that a layout that minimizes material transfer costs when considering only loaded trips (static design criteria) may have much higher WIP inventory (stochastic operational performance measure) than another layout that may not minimize (loaded) material transfer costs. In fact, it is quite possible that a layout that minimizes loaded material transfer costs might be infeasible in the sense that it leads to an infinite WIP accumulation at one or more machines.

To summarize, the potential to frequently alter layouts, therefore, in a sense, transforms the modern layout problem from a strategic problem in which only long-term material handling costs are considered to a tactical problem in which operational performance measures such as reduction of product flow times, WIP inventories, and maximizing throughput rate are considered in addition to material handling and machine relocation costs when changing from one layout configuration to the next.

Meng *et al.* [1] have proposed a three-phase procedure for the design and analysis of next-generation factory layouts. In the first phase, multiple, alternate layouts that perform well with respect to static design criteria are generated using available algorithms for facility layout. In the second phase, each alternate layout is evaluated with respect to several stochastic operational performance measures. The manufacturing system performance analyzer (MPA) developed for analytically evaluating the performance of a layout is an extension of Whitt's [35] queueing network analyzer (QNA) [36,37]. Because MPA also incorporates the factors such as empty travel time of the material handling device, setup, machine

failures, and batching, it is a more realistic, comprehensive, and accurate tool. MPA not only determines the performance measures analytically but also provides simulation results for the same performance measures using ProModel software.

The analysis from phases 1 and 2 are combined to rank-order a set of three or so layouts that perform well with respect to the user-weighted design and operational performance criteria.

SUMMARY

Because of continuous changes in product mix, volume, and manufacturing requirements, next-generation facility layouts that are robust for multiple production periods or scenarios or are flexible and therefore can be reconfigured with minimal effort to meet the production requirement changes are preferred. When evaluating the candidate layouts, their performance relative to stochastic performance measures must also be considered. For example, WIP inventory level and cycle time evaluations, in addition to static material handling costs make a layout analysis more comprehensive. As a performance evaluation tool of facility layouts, MPA is a powerful tool for reconfigurable layout problems.

MARKOV AND HIDDEN MARKOV MODELS

REFIK SOYER

Department of Decision Sciences,
The George Washington
University, Washington, DC

INTRODUCTION AND OVERVIEW

Stochastic process models are fundamental for assessing the reliability of items that operate under a dynamic environment. As pointed out by Singpurwalla [1], since the dynamic environment causes changes in the physics of failure, use of stochastic processes provides flexibility in describing failure characteristics under these environments. Earlier uses of stochastic process models include Mercer [2] who modeled item wear and Klein [3] who used a Markov chain (MC) model to describe stochastic deterioration of a system. Gaver [4] is the first who proposed modeling the failure rate as a stochastic process and introduced the notion of a *randomly changing environment*.

Assessment of reliability of an item/system as a function of the stochastic process governing the environment was considered by Çinlar [5–7], and the notion further developed by Çinlar and Özekici [8] who considered models of stochastic dependence caused by a random environment. The model of Çinlar and Özekici [8] is studied further in Çinlar *et al.* [9]. Related developments are those by Lindley and Singpurwalla [10], and by Singpurwalla and Youngren [11]. Özekici [12] analyzed the optimal maintenance problem of a single-component device operating in a random environment. In all these cases, the environment is characterized by a stochastic process model; see Singpurwalla [1], for a survey. Recent work in stochastic hazard processes can be found in Özekici [13].

Note that a stochastic process is a collection of random variables that are

indexed by a parameter space T . In our setup the parameter space T will be time which could be discrete, say $T = I = (0, 1, 2, \dots)$, or continuous, say $T = \mathbb{R}^+ = (t; 0 \leq t < \infty)$. In our notation, the collection of random variables $X_0, X_1, \dots, X_n, \dots$, will denote a discrete-time stochastic process, $\{X_n; n \in I\}$, whereas the collection $\{Y_t; t \in \mathbb{R}^+\}$ denotes a continuous-time stochastic process. The state space E of the stochastic process, that is, the possible set of values that either X_n or Y_t can take, can be discrete or continuous. When E is discrete, the process $\{X_n; n \in I\}$ is said to be a discrete-state, discrete-time stochastic process, and $\{Y_t; t \in \mathbb{R}^+\}$ is a discrete-state, continuous-time process. Similarly, when E is continuous the process $\{Y_t; t \in \mathbb{R}^+\}$ is referred to as a continuous-state, continuous-time process.

Of the several stochastic process models that have been considered by the above authors, the simplest is the Markov process (MP), but many stochastic models used in reliability analysis belong to the Markov class. Important examples include discrete and continuous-time Markov chains (CTMCs) and diffusion processes. The section titled “Markov Processes” gives an overview of Markov processes and discusses some of the widely used examples. Most of the material in this section can be found in Çinlar [14], Karlin and Taylor [15], or Ross [16].

Stochastic processes that are governed by MPs, which cannot be observed, are referred to as *hidden Markov models* (HMMs) [17]. Such processes have found applications in areas such as speech recognition [18], signal processing [19], biology and medicine [20], environmental sciences [21], software engineering [22–24] and have been of interest to statisticians [25–28] because of the difficult inferential issues that they pose. An excellent book on the HMMs is by Elliot *et al.* [29]. The HMMs will be discussed in the section titled “Hidden Markov Models”. An application of the HMMs to software reliability analysis is presented in the section titled “Application of HMMs in Software Reliability”.

MARKOV PROCESSES

The stochastic process $\{Z_t; t \in T\}$ is said to be an MP if for any $t, s \in T$ and for any set of states $A \in E$,

$$P(Z_{t+s} \in A | Z_u; u \leq t) = P(Z_{t+s} \in A | Z_t). \quad (1)$$

The above relationship is referred to as the *Markov property*. It simply states that given the present the future of the process is independent of the past. If Equation (1) is independent of t , then the MP is said to be time-homogeneous.

A continuous-time MP, Z_t , with continuous state space E is called a *diffusion process*. Diffusion processes are used to describe item wear and system degradation over time [30]. Brownian motion is the most commonly used diffusion process for modeling such phenomena. An important class of MPs are processes with *independent increments*. A continuous-time stochastic process Z_t will have independent increments if for all $t_1 < t_2 < \dots < t_n$ the random variables Z_{t_1} , $Z_{t_2} - Z_{t_1}, \dots, Z_{t_n} - Z_{t_{n-1}}$ are independent [16]. Furthermore, the process will have *stationary increments* if the distribution of $(Z_{t+s} - Z_t)$ does not depend on t . It is easy to see that every stochastic process Z_t with independent increments is an MP. Brownian motion process has independent increments.

Another process with the independent increments property is the gamma process [31]. As noted by Singpurwalla [1] and Park and Padgett [30], the Gaussian assumption of increments in the Brownian motion makes it an unattractive choice for modeling wear and degradation since the process is not monotonically increasing. One way to alleviate this is to use a geometric Brownian motion or a gamma process as suggested in Park and Padgett [30]. As pointed by the authors, the gamma process is more desirable than the geometric Brownian motion since it is always positive and increasing.

The original use of gamma process for describing deterioration goes back to Abdel-Hameed [32]. A gamma process Z_t has the following properties:

1. $Z_0 = 0$;
2. Z_t has independent increments;
3. $(Z_t - Z_s)$ has a gamma distribution $G[(a_t - a_s), b]$ with shape parameter $(a_t - a_s) > 0$ and scale parameter $b > 0$ for all $t > s$.

An excellent review of gamma processes and their use in maintenance is given in van Noortwijk [33].

Markov Chains

An MP with discrete state space E is called a *Markov chain*. If the process is a discrete-time process, that is, if $T = I$ then the process is called a *discrete-time Markov chain* or more commonly a *Markov chain*. More specifically, a stochastic process $\{X_n; n \in I\}$ is said to be an MC, with state space E , if for all $n, m \in I$, and $(x_1, x_2, \dots) \in E$,

$$\begin{aligned} P(X_{n+m} = x_{n+m} | X_n = x_n, \dots, X_0 \\ = x_0) = P(X_{n+m} = x_{n+m} | X_n = x_n). \end{aligned} \quad (2)$$

The MC is said to be time-homogeneous, if the above relationship is independent of n , that is,

$$P(X_{n+m} = j | X_n = i) = P_m(i, j),$$

where $P_m(i, j)$ is called the *m-step transition probability* of the MC. Also, $P(i, j) = P_1(i, j)$ is called the *transition probability* from state i to state j of the time-homogeneous MC, that is,

$$\begin{aligned} P(X_{n+1} = j | X_n = i, \dots, X_0) \\ = P(X_{n+1} = j | X_n = i) = P(i, j). \end{aligned}$$

The matrix $\mathbf{P}$, whose (i, j) th element is $P(i, j)$ is called the *transition probability matrix* of the MC. Note that $P(i, j) \geq 0$, for any $i, j \in E$ and $\sum_{j \in E} P(i, j) = 1$.

A continuous-time discrete state space MP, Y_t , is called a *continuous-time Markov chain*. Our discussion of CTMCs in the Section titled “Continuous-Time Markov Chains” is based on Ref. 17.

Continuous-Time Markov Chains

The stochastic process $\{Y_t; t \in \mathbb{R}^+\}$ is said to be a CTMC with discrete state space E , if for any $j \in E$, and $t, s \in \mathbb{R}^+$

$$P(Y_{t+s} = j | Y_u; u \leq t) = P(Y_{t+s} = j | Y_t). \quad (3)$$

If the above relationship does not depend on t , then the CTMC is said to be *time-homogeneous*, and we write,

$$P(Y_{t+s} = j | Y_t = i) = P_s(i, j).$$

where $P_s(i, j)$ is called the *transition function* of the CTMC and it has the following properties:

1. $P_s(i, j) \geq 0$
2. $\sum_{j \in E} P_s(i, j) = 1$
3. $P_{r+s}(i, j) = \sum_{k \in E} P_r(i, k) P_s(k, j)$.

The relationship (3) above is called the *Chapman—Kolmogorov equation*.

A CTMC with

$$P(Y_{t+s} = j | Y_t = i) = \begin{cases} P_s(i, j) = 0, & \text{if } j < i \\ \frac{e^{-\lambda s} (\lambda s)^{j-i}}{(j-i)!}, & \text{if } j \geq i, \end{cases} \quad (4)$$

is known as a homogeneous *Poisson process* for some constant $\lambda > 0$.

Associated with any CTMC, is a discrete parameter, discrete-state stochastic process $\{X_n; n \in I\}$, where X_n can be constructed from the process $\{Y_t; t \in \mathbb{R}^+\}$ as follows:

$$X_n = Y_{T_n}, \text{ for } T_n \leq t < T_{n+1}, \quad n = 0, 1, 2, \dots, \quad (5)$$

where $0 \equiv T_0 < T_1 < \dots < T_n < T_{n+1} < \dots$ are the times at which the CTMC changes states. The process $\{X_n; n \in I\}$ keeps track of the various states that the process $\{Y_t; t \in \mathbb{R}^+\}$ takes over time starting with the initial state Y_{T_0} at time 0. The process $\{X_n; n \in I\}$ is said to be *engendered* by the process $\{Y_t; t \in \mathbb{R}^+\}$ and has certain properties.

Result 1. Suppose that $\{Y_t; t \in \mathbb{R}^+\}$ is a CTMC with state space E . Let $\{X_n; n \in I\}$ be the corresponding discrete parameter process that is engendered by the above CTMC via the tracking scheme mentioned before. Then, $\{X_n; n \in I\}$ is an MC with some transition matrix $\mathbf{P}$, where $P(i, j) \geq 0$, for $i \neq j$, $P(i, i) = 0$, and $\sum_{j \in E} P(i, j) = 1$.

Thus, the Markov property of the $\{Y_t; t \in \mathbb{R}^+\}$ process is inherited by its engendered $\{X_n; n \in I\}$ process. The process $\{X_n; n \in I\}$ is called the *embedded chain* of the CTMC.

Result 2. For any $u \geq 0$, and a constant $\mu(i) > 0$,

$$P(T_{n+1} - T_n \geq u \mid X_{n+1} = j, X_n = i) = e^{-\mu(i)u}.$$

Thus the sojourn times in a CTMC have an exponential distribution whose scale parameter depends only on the current state i ; it does not depend on the next state j to which X_n is going to make a transition. Thus μ needs only be indexed by i .

Result 3. For any $u_i \geq 0$, $i = 1, 2, \dots$, and $\mu(i_j) > 0$, $j = 0, 1, 2, \dots$

$$\begin{aligned} P(T_1 - T_0 \geq u_1, T_2 - T_1 \geq u_2, \dots, \\ T_n - T_{n-1} \geq u_n \mid X_0 = i_0, \dots, X_n = i_n) \\ = \exp(-\mu(i_0)u_1) \exp(-\mu(i_1)u_2) \dots \\ \exp(-\mu(i_{n-1})u_n). \end{aligned}$$

That is, the sojourn times of a CTMC are, conditional on $X_0, \dots, X_n$, independently, but not identically exponentially distributed. The scale parameters of the exponential distributions depend only on the current states of the X_i 's.

The next result pertains to the joint distribution of the sojourn time in a state, and the state to which the CTMC is going to make a transition to.

Result 4. For any $i, j \in E$, and $u \geq 0$

$$\begin{aligned} P(X_{n+1} = j, T_{n+1} - T_n \geq u \mid X_0, \dots, \\ X_n, T_0, \dots, T_n) \\ = P(X_{n+1} = j, T_{n+1} - T_n \geq u \mid X_n = i) \\ = P(i, j) e^{-\mu(i)u}. \end{aligned}$$

Thus for a CTMC, the said joint distribution depends only on the current state of the process i , via the $\mu(i)$, and the transition probability matrix $\mathbf{P}$ of the embedded chain. Furthermore, the transition to a particular state is independent of the time spent in the current state.

In principle, we should be able to obtain results parallel to those of the four results for processes other than the Markov. However, the attractive properties of inheriting the Markovian feature, the exponentiality and the (conditional) independence of the sojourn times, and the (conditional) independence between the sojourn time and the state transitioned to, may be lost; see Limnios [34] for *semi-Markov processes*. Finally, since homogeneous Poisson processes with the parameter $\lambda > 0$ is a special case of the CTMC, our Results 2, 3, and 4 simplify with all the $u(\cdot)$'s replaced by a common λ . Consequently, here, conditioning on the current state does not matter. Furthermore, in the case of a Poisson process $P(i, j) = 1$, only if $j = i + 1$; otherwise it is zero.

The Generator of CTMC and Markovian Analysis

Analogous to the notion of a transition probability matrix of a MC, is the notion of a transition rate matrix of a CTMC. Specifically, the matrix $\mathbf{P}_s$, whose (i, j) th element is $P_s(i, j)$ is of relevance for studying several characteristics of a CTMC. Recall that $P_s(i, j)$ is the probability that the CTMC transitions from state i to state j in a time interval of length s .

Result 5. For any $i, j \in E$, $P_s(i, j)$ is differentiable, and $\lim_{s \rightarrow 0} \frac{d}{ds} P_s(i, j) = A(i, j) = \mu(i)[P(i, j) - I(i, j)]$, where $I(i, j) = 1$, if $j = i$, and is zero otherwise. Thus,

$$A(i, j) = \begin{cases} -\mu(i), & \text{if } j = i \\ \mu(i)P(i, j), & \text{if } j \neq i. \end{cases}$$

Consequently, if $P_s(i, j)$ is known for every $i, j \in E$, then $A(i, j)$ is known, and from there we know $\mu(i)$ and $P(i, j)$. Thus a knowledge of the transition probability matrix $\mathbf{P}_s$ of the CTMC enables us to obtain the transition probability matrix $\mathbf{P}$ of the embedded chain,

and also, the $\mu(i)$'s, the scale parameters of the distributions of the sojourn times of the process. Conversely, if E is a finite set of say m elements, then a knowledge of $\mu(1), \dots, \mu(m)$, and $\mathbf{P}$ enables us to obtain $\mathbf{A}$, the matrix whose (i, j) th element is $A(i, j)$. Once $\mathbf{A}$ is known, we may obtain the matrix $\mathbf{P}_s$ via the *matrix-exponential* relationship

$$\mathbf{P}_s = e^{s\mathbf{A}} = \sum_{k=0}^{\infty} \frac{s^k \mathbf{A}^k}{k!};$$

where the summation is a consequence of the Taylor series expansion of $e^{s\mathbf{A}}$. The above development is known as a *Markovian analysis*. The matrix $\mathbf{A}$ is called the *generator* of the CTMC.

HIDDEN MARKOV MODELS

As previously pointed out, HMMs are stochastic processes that are governed by MPs, which cannot be observed. Examples of HMMs include Markov modulated Bernoulli processes (MMBPs) [27,35], where the governing or modulating process is an MC and Markov modulated Poisson processes (MMPPs) [36] where the modulating process is a CTMC. It is important to note that here we use the term HMM or a Markov modulated process in a more general manner to include any MP as a governing process. Sometimes in the literature, the term HMM is used to refer only to discrete-time processes governed by MCs [28], whereas the term Markov modulated process is reserved for the case where the governing process is a CTMC [37].

In reliability modeling, the HMMs are sometimes referred to as *random environment models* as in Özekici and Soyer [38]. In Özekici and Soyer [38] the item/system in question is assumed to operate in a randomly changing environment depicted by $\{Y_t; t \in \mathbb{R}^+\}$, where Y_t is the state of the environment at time t . The environmental process Y is an MP with some state space E , which is assumed to be discrete to simplify the notation. Note that if the environmental process is assumed to be a semi-MP, then the resulting processes will be hidden semi-Markov models as considered by Limnios [34] and Özekici and Soyer [39].

In what follows, we assume that the environmental process Y is an MP and we consider the MMPP and the MMBP. As noted in Singpurwalla *et al.* [17], MMPP is a special case of the *Markov renewal process* (MRP) of Çinlar [5] as well as the *doubly stochastic Poisson process* of Kingman [40], which is also known as the *Cox process*.

Markov Modulated Poisson Model

Let N be a modulated Poisson process such that N_t depicts the total number of arrivals until time t . The modulation is done via an environmental process Y with a discrete state space E where Y_t represents the state of the environment at time t . The rate of arrivals at time t is $\lambda(Y_t)$ for some arrival rate vector λ defined on E . We suppose that while the environment is at state i arrivals occur according to an ordinary Poisson process with rate $\lambda(i)$. To be more precise,

$$P(N_t = k | Y) = \frac{e^{-H_t} H_t^k}{k!}, \quad (6)$$

where

$$H_t = \int_0^t \lambda(Y_s) ds, \quad (7)$$

for all $k = 0, 1, \dots$, and $t \geq 0$.

It follows from the above that, given Y , N is a nonstationary Poisson process with mean value function $E(N_t | Y) = H_t$. Defining T to be the arrival time process so that T_n is the time of the n th arrival, we have the conditional interarrival time distribution

$$P(T_{n+1} - T_n > t | Y, T_n) = e^{-(H_{T_n+t} - H_{T_n})}. \quad (8)$$

The modulated process reduces to the ordinary Poisson process with rate λ if the arrival rate vector is $\lambda(i) = \lambda$ independent of the environment for all i . In this case, $H_t = \lambda t$ deterministically.

The arrival process N can be studied via the additive functional H of Y . In particular, Equations (6) and (8) directly yield

$$P(N_t = k) = E \left(\frac{e^{-H_t} H_t^k}{k!} \right) \quad (9)$$

and

$$P(T_{n+1} - T_n > t | T_n) = E(e^{-(H_{T_n+t} - H_{T_n})}). \quad (10)$$

Therefore, the probability law of H , thus, that of the environmental process Y , will play an important role in our analysis of N and T .

We assume that Y is an MP with an embedded MC X and jump times S . In other words, X_n is the n th state visited by the environmental process and S_n is the time of this visit such that,

$$Y_t = X_n \text{ whenever } S_n \leq t < S_{n+1}. \quad (11)$$

If $\mathbf{P}$ is the transition matrix of the embedded MC X , and μ is the vector of jump rate, then transition function of the Y process is given by

$$P(Y_t = j | Y_0 = i) = P(i, j)(1 - e^{-\mu(i)t}). \quad (12)$$

More precisely, if the process Y is in some state i , then it stays there for an exponentially distributed amount of time with rate $\mu(i)$ and then jumps to some other state j with probability $P(i, j)$. It also follows that

$$F_i(t) = P(S_1 \leq t | Y_0 = i) = 1 - e^{-\mu(i)t} \quad (13)$$

and the generator of the MP Y is given by the matrix

$$A(i, j) = \begin{cases} -\mu(i), & \text{if } j = i \\ \mu(i)P(i, j), & \text{if } j \neq i. \end{cases} \quad (14)$$

Let P_t denote the transition function of Y given by Equation (12), that is,

$$P_t(i, j) = P(Y_t = j | Y_0 = i). \quad (15)$$

Following Özekici and Soyer [39], we define another process Y^λ such that

$$Y_t^\lambda = \begin{cases} Y_t, & \text{if } t < T_1, \\ \Delta, & \text{if } t \geq T_1, \end{cases} \quad (16)$$

where T_1 is the time of the first arrival. While the environment is in state i , the time of arrival has the exponential distribution with rate $\lambda(i)$. It is clear that Y^λ is also an MP on the extended state space $E_\Delta = E \cup \{\Delta\}$ and it is obtained by “stopping” the MP Y as soon

as an arrival occurs. Here, Δ is an absorbing state where the process is dumped to as soon as it is stopped. The transition matrix of the embedded MC is now extended as

$$P_\lambda(i, j) = \begin{cases} \frac{\mu(i)}{\mu(i) + \lambda(i)} P(i, j), & \text{if } i, j \in E \\ \frac{\lambda(i)}{\mu(i) + \lambda(i)}, & \text{if } i \in E, j = \Delta \\ 1, & \text{if } i, j = \Delta \end{cases} \quad (17)$$

and the transition rate vector is

$$\mu_\lambda(i) = \begin{cases} \mu(i) + \lambda(i), & \text{if } i \in E \\ 0, & \text{if } i = \Delta. \end{cases} \quad (18)$$

If we let the matrix $A_\lambda(i, j) = \mu_\lambda(i)(P_\lambda(i, j) - I(i, j))$ denote the generator of Y^λ , then it is well known that the transition function $P_t^\lambda(i, j) = P(Y_t^\lambda = j | Y_0^\lambda = i)$ for all $i, j \in E_\Delta$ is given by the matrix-exponential solution

$$P_t^\lambda = e^{A_\lambda t} = \sum_{n=0}^{+\infty} \frac{t^n}{n!} A_\lambda^n. \quad (19)$$

A further simplification is obtained by noting that

$$A_\lambda(i, j) = A(i, j) - \Lambda(i, j), \quad (20)$$

for all $i, j \in E$ where Λ is a diagonal matrix defined as

$$\Lambda(i, j) = \begin{cases} \lambda(i), & \text{if } j = i \\ 0, & \text{if } j \neq i. \end{cases} \quad (21)$$

Since $A_\lambda(\Delta, j) = 0$ and $A_\lambda(i, \Delta) = \lambda(i)$ for all $i \in E$ and $j \in E_\Delta$, we can rewrite Equation (19) as

$$P_t^\lambda(i, j) = e^{A_\lambda t}(i, j) = e^{(A - \Lambda)t}(i, j) \quad (22)$$

for all $i, j \in E$.

Now, note that our construction of Y^λ implies

$$T_1 = \inf\{t \geq 0; Y_t^\lambda = \Delta\} \quad (23)$$

and T_1 is the first-passage time to the absorbing state Δ . So, it has a phase-type distribution and, in particular,

$$\begin{aligned} P_i(T_1 > t) &= P_i(Y_t^\lambda \in E) = \sum_{j \in E} P_t^\lambda(i, j) \\ &= \sum_{j \in E} e^{(A - \Lambda)t}(i, j). \end{aligned} \quad (24)$$

Note that in reliability applications where a device fails exponentially with a failure rate that depends on the randomly changing environment, Equation (24) gives the survival function. In this case, the mean time to failure is another quantity of interest. Using the Markov property, it can be computed by solving the system of linear equations

$$E_i(T_1) = \mu_\lambda(i)^{-1} + \sum_{j \in E} P_\lambda(i, j) E_j(T_1), \quad (25)$$

for $i \in E$ so that the explicit solution is

$$E_i(T_1) = \sum_{j \in E} [I - P_\lambda]^{-1}(i, j) \mu_\lambda(j)^{-1}. \quad (26)$$

Following Özekici and Soyer [39] an ergodic analysis can be developed. Suppose that both X and Y are ergodic processes with limiting distributions $\nu(j) = \lim_{n \rightarrow +\infty} P(X_n = j)$ and $\pi(j) = \lim_{t \rightarrow +\infty} P(Y_t = j)$. This implies that ν is the unique solution of $\nu = \nu \mathbf{P}$ with the normalizing condition $\sum_{i \in E} \nu(i) = 1$. It can be shown that

$$\pi(j) = \frac{\nu(j)/\mu(j)}{\sum_{k \in E} (\nu(k)/\mu(k))}. \quad (27)$$

Using Theorem 1 of Özekici and Soyer [39], we can obtain

$$\lim_{t \rightarrow +\infty} E_i(N_t - \hat{\lambda}t) = \sum_{j \in E} \pi(j) \left[\frac{\hat{\lambda} - \lambda(j)}{\mu(j)} \right] \quad (28)$$

and

$$\lim_{t \rightarrow +\infty} \frac{E_i(N_t)}{t} = \hat{\lambda} = \sum_{j \in E} \pi(j) \lambda(j). \quad (29)$$

It follows from Fischer and Meier-Hellstern [36], the expected number of arrivals until time t is

$$E_i(N_t) = \hat{\lambda}t + \sum_{j \in E} \left([e^{At} - I] [A + \Pi]^{-1} \right)(i, j) \lambda(j) \quad (30)$$

where $\Pi(i, j) = \pi(j)$.

Markov Modulated Bernoulli Process

We now consider discrete-time models for systems observed periodically at discrete time points. The system survives each period with a probability that depends on the state of the prevailing environment in that period. Since each period ends with a failure or survival, one can model this system as a Bernoulli process where the success probability is modulated by the environmental process. Using this setup with a Markovian environmental process, Özekici [35] focuses on probabilistic modeling and provides a complete transient and ergodic analysis. We assume throughout the following discussion the sequence of environmental states $\{Y_t; t \in I\}$ is a MC with some transition matrix $\mathbf{P}$ on a discrete state space E .

Consider a system observed periodically at times $t = 1, 2, \dots$, and the state of the system at time t is described by a Bernoulli random variable

$$X_t = \begin{cases} 1, & \text{if system is not functioning at time } t \\ 0, & \text{if system is functioning at time } t. \end{cases}$$

Given that the environment is in some state i at time t , the probability of failure in the period is

$$P(X_t = 1 | Y_t = i) = \pi(i) \quad (31)$$

for some $0 \leq \pi(i) \leq 1$. The states of the system at different points in time constitute a Bernoulli process $X = \{X_t; t = 1, 2, \dots\}$ where the success probability is a function of the environmental process Y .

Given the environmental process Y , the random quantities $X_1, X_2, \dots$, represent a conditionally independent sequence, that is,

$$\begin{aligned} P(X_1 = x_1, X_2 = x_2, \dots, X_n = x_n | Y) \\ = \prod_{k=1}^n P(X_k = x_k | Y). \end{aligned} \quad (32)$$

In the above setup, the reliability of the system is modulated by the environmental process Y , which is assumed to be an MP and thus the model is referred to as the *Markov*

modulated Bernoulli process (MMBP). If the system fails in a period, then it is replaced immediately by an identical one at the beginning of the next period. It may be possible to think of the environmental process Y as a random mission process such that Y_t is the t th mission to be performed. The success and failure probabilities depend on the mission itself. If the device fails during a mission, then the next mission will be performed by a new and identical device.

If we denote the lifetime of the system by L , then the conditional life distribution is

$$\begin{aligned} P(L = m | Y) \\ = \begin{cases} \pi(Y_1), & \text{if } m = 1 \\ \pi(Y_m) \prod_{j=1}^{m-1} (1 - \pi(Y_j)), & \text{if } m \geq 2. \end{cases} \end{aligned} \quad (33)$$

Note that if $\pi(i) = \pi$ for all $i \in E$, that is, the system reliability is independent of the environment, then Equation (33) is simply the geometric distribution $P(L = m | Y) = \pi(1 - \pi)^{m-1}$. We can also write

$$\begin{aligned} P(L > m | Y) &= (1 - \pi(Y_1))(1 - \pi(Y_2)) \dots \\ &\quad (1 - \pi(Y_m)), \end{aligned} \quad (34)$$

for $m \geq 1$.

We represent the initial state of the MC by Y_1 , rather than Y_0 , as it is customarily done in the literature, so that it represents the first environment that the system operates in. Thus, most of our analysis and results will be conditional on the initial state Y_1 of the MC. Therefore, for any event A and random variable Z we set $P_i(A) = P(A | Y_1 = i)$ and $E_i(Z) = P(Z | Y_1 = i)$ to express the conditioning on the initial state.

As pointed out by Özekici [35], the life distribution satisfies the recursive expression

$$\begin{aligned} P_i(L > m + 1) \\ = (1 - \pi(i)) \sum_{j \in E} P(i, j) P_j(L > m) \end{aligned} \quad (35)$$

with the obvious boundary condition $P_i(L > 0) = 1$. The survival probabilities can be explicitly computed via

$$P_i(L > m) = \sum_{j \in E} Q_0^m(i, j), \quad (36)$$

where $Q_0(i, j) = (1 - \pi(i))P(i, j)$. Using Equation (36), the conditional expected lifetime can be obtained as

$$E_i(L) = \sum_{m=0}^{+\infty} \sum_{j \in E} Q_0^m(i, j) = \sum_{j \in E} R_0(i, j), \quad (37)$$

where $R_0(i, j) = \sum_{m=0}^{+\infty} Q_0^m(i, j) = (I - Q_0)^{-1}(i, j)$ is the potential matrix corresponding to Q_0 .

APPLICATION OF HMMS IN SOFTWARE RELIABILITY

The notion of an *operational profile* was introduced by Musa *et al.* [41]. An operation is an externally initiated task performed by a system “as built”. The operational profile of any software describes how users employ the system. It is a quantitative and probabilistic characterization of how a system will be used. An operational profile is defined as a set of operations and the probabilities of their occurrence [42].

Optimal testing problems involving operational profiles are discussed in detail in Özekici and Soyer [22] and Özekici *et al.* [43]. Once testing is completed, the software is released to the users. This is done in an uncontrolled setting and the sequence of operations as well as their durations are now random. This operational process or the environmental process now modulates the parameters of the reliability model and plays a crucial role in software reliability assessment. Now, the environmental state Y_t at time t represents the operation performed by the user. The analysis of the software failure process obviously depends on the stochastic structure of the operational process.

In Özekici and Soyer [44], Y is assumed to be an MP. Briefly, this means that the sequence of operations performed is an MC and the amount of time spent on each operation is exponentially distributed. More precisely, we let X_n denote the n th operation that the system performs and T_n be the time at which the n th operation starts. Following our development, X is an MC with some transition matrix

$$P(i, j) = P(X_{n+1} = j | X_n = i) \quad (38)$$

and

$$P(T_{n+1} - T_n > t | X_n = i) = e^{-\mu(i)t}, \quad (39)$$

so that the duration of the n th operation is exponentially distributed with rate $\mu(i)$ if this operation is i . The probabilistic structure of the operational process is given by the generator $A(i, j) = \mu(i)(P(i, j) - I(i, j))$, where I is the identity matrix.

An overview of software failure models is presented in Singpurwalla and Soyer [45]. Perhaps the most important aspect of these models is related to the stochastic structure of the underlying failure process. This could be a “times-between-failures” model, which assumes that the times between successive failures follow a specific distribution whose parameters depend on the number of faults remaining in the program after the most recent failure. One of the most celebrated failure models in this group is that of Jelinski and Moranda [46] where the basic assumption is that there are a fixed number of initial faults in the software and each fault causes failures according to a Poisson process with the same failure rate. After each failure, the fault causing the failure is detected and removed with certainty so that the total number of faults in the software is decreased by one. In the present setting, the time to failure distribution for each fault in the software is exponentially distributed with parameter $\lambda(k)$ during operation k and this results in an extension of the Jelinski—Moranda model.

In dealing with software reliability, one is interested in the number of faults N_t remaining in the software at time t . Then, N_0 is the initial number of faults and the process $\{N_t; t \in \mathbb{R}^+\}$ depicts the stochastic evolution of the number of faults. If there is perfect debugging, then N decreases as time goes on, eventually to diminish to zero. Defining the bivariate process $Z_t = (Y_t, N_t)$, it follows that $Z = (Y, N)$ is an MP with discrete state space $F = E \times \{0, 1, 2, \dots\}$. As pointed out in Özekici and Soyer [44], this follows by noting that Y is an MP and N is a process that decreases by 1 after an exponential amount of time with a rate that

depends only on the state of Y . In particular, if the current state of Z is (i, n) for any $n > 0$, then the next state is either (j, n) with rate $\mu(i)P(i, j)$ or $(i, n-1)$ with rate $n\lambda(i)$. If $n = 0$, then the next state is $(j, 0)$ with rate $\mu(j)$. Note that 0 is an absorbing state for N .

This implies that the sojourn in state (i, n) is exponentially distributed with rate

$$\beta(i, n) = \mu(i) + n\lambda(i) \quad (40)$$

and the generator Q of Z is

$$Q((i, n), (j, m)) = \begin{cases} -(\mu(i) + n\lambda(i)), & j = i, m = n \\ \mu(i)P(i, j), & j \neq i, m = n \\ n\lambda(i), & j = i, m = n - 1 \end{cases} \quad (41)$$

Reliability is defined as the probability of failure free operation for a specified time. We will denote this by the function

$$\begin{aligned} R(i, n, t) &= P(L > t | Y_0 = i, N_0 = n) \\ &= P(N_t = n | Y_0 = i, N_0 = n), \end{aligned} \quad (42)$$

defined for all $(i, n) \in F$ and $t \geq 0$. Note that this is equal to the probability that there will be no arrivals until time t in a MMPP with intensity function $\hat{\lambda}(t) = n\lambda(Y_t)$. Thus, following Fischer and Meier-Hellstern [36], we can obtain the explicit formula

$$R(i, n, t) = \sum_{j \in E} \left[e^{(A - n\Lambda)t} \right]_{ij}, \quad (43)$$

where

$$e^{(A - n\Lambda)t} = \sum_{k=0}^{+\infty} \frac{t^k}{k!} (A - n\Lambda)^k \quad (44)$$

is the exponential matrix and $\Lambda(i, j) = \lambda(i)I(i, j)$.

MARKOV CHAINS OF THE M/G/1-TYPE

DARIO ANDREA BINI
BEATRICE MEINI
Dipartimento di Matematica,
Università di Pisa, Pisa, Italy

M/G/1-type Markov chains are a generalization of M/G/1 Markov chains obtained by replacing the one-dimensional state space of the latter with a bidimensional state space. Thus, the transition matrix of an M/G/1-type Markov chain is a block generalization of the transition matrix of an M/G/1 Markov chain.

M/G/1-type Markov chains [1] have been introduced and analyzed by Marcel F. Neuts, and model a large number of queueing problems from telecommunications, engineering, and applied sciences. The specific features of M/G/1-type Markov chains and the strong structure of the transition matrix have been further exploited by many authors. Several interesting results have been obtained both from the theoretical and computational points of view along with the design of highly efficient algorithms for computing the steady-state vector and other measures of interest. The rich mathematical structure of M/G/1-type Markov chains still provides several interesting theoretical problems and computational challenges.

The analysis of M/G/1-type Markov chains, performed through matrix analytic methods, provides very effective theoretical and computational tools to treat some structured Markov chains. This methodology provides also a systematic way of approaching problems related to both transient and steady-state results for a wide class of structured Markov renewal processes [2]. The algorithms obtained in this framework, endowed with very high efficiency, can be described both with the language of applied probability and of numerical analysis. The different points of view enable one to better

understand the deep features and the elegance of these algorithms [3].

In this article, we report the main theoretical properties and the up-to-date solution algorithms concerning discrete-time M/G/1-type Markov chains. In the section titled “Definitions” we recall the definitions and assumptions used in the sequel of the article. In the section titled “Positive Recurrence,” the necessary and sufficient conditions for positive recurrence are given. The section titled “Steady-State Vector” reports the main properties of the steady-state vector. The section titled “Transformation into QBD” describes a general reduction of an M/G/1-type Markov chain to a QBD (Quasi birth-death process). The section titled “Numerical Methods” is devoted to numerical methods for solving M/G/1-type Markov chains. We describe the classical approach of fixed-point iteration and fast methods based on the doubling strategy and acceleration techniques together with a description of the currently available software. The last section reports on further reading.

DEFINITIONS

Let $\mathbb{N} = \{0, 1, 2, \dots\}$ be the set of natural numbers, $\mathbb{N}^+$ the set of positive natural numbers, and $S_m = \{1, 2, \dots, m\}$. An M/G/1-type Markov chain is a two-dimensional process (X_n, φ_n) on the state space $E = (\{0\} \times S_{m_0}) \cup (\mathbb{N}^+ \times S_m)$, with transition matrix

$$P = \begin{bmatrix} B_0 & B_1 & B_2 & B_3 & \dots \\ C & A_0 & A_1 & A_2 & \ddots \\ & A_{-1} & A_0 & A_1 & \ddots \\ & & A_{-1} & A_0 & \ddots \\ 0 & & & \ddots & \ddots \end{bmatrix}, \quad (1)$$

where B_0 is an $m_0 \times m_0$ matrix, $B_i, i \geq 1$ are $m_0 \times m$ matrices, C is an $m \times m_0$ matrix, and $A_i, i \geq -1$ are $m \times m$ matrices such that P

is stochastic. Each state of the Markov chain is formed by a pair (i, j) where $i \in \mathbb{N}^+$ and $j \in S_m$, or $i = 0$ and $j \in S_{m_0}$; moreover, $\mathbb{N}$ is called *level set* and S_m, S_{m_0} are called *phase sets*.

In particular, one has

$$(B_0)_{jj'} = P[X_{n+1}=0, \varphi_{n+1}=j' | X_n=0, \varphi_n=j], \\ j, j' \in S_{m_0},$$

$$(C)_{jj'} = P[X_{n+1}=0, \varphi_{n+1}=j' | X_n=1, \varphi_n=j], \\ j \in S_m, \quad j' \in S_{m_0},$$

$$(A_k)_{jj'} = P[X_{n+1}=i+k, \varphi_{n+1}=j' | X_n=i, \\ \varphi_n=j], \quad (i, k) \neq (1, -1), \\ k \geq -1, \quad i \geq 1, \quad j, j' \in S_m,$$

$$(B_k)_{jj'} = P[X_{n+1}=k, \varphi_{n+1}=j' | X_n=0, \varphi_n=j], \\ k \geq 1, \quad j \in S_{m_0}, j' \in S_m.$$

In other words, if the Markov chain is in the nonboundary level $i \geq 1$, then A_{-1} gives the transition probabilities down by one level and A_k , for $k \geq 0$, gives the transition probabilities up by k levels, while B_k gives the transition probabilities up by k levels, starting from the boundary level 0.

Observe that P is an upper block Hessenberg matrix; that is, the blocks of P below the subdiagonal are zero. This structure implies that starting in level k at time n , the process may move to any higher level at time $n+1$, but it may not move in one step beyond $k-1$ toward lower levels.

Another feature of P is that, except for the blocks in the first block row and block column, the block entries of P are constant along the block diagonals. A matrix with this structure is called *block Toeplitz*. The block Toeplitz structure implies that the transition probabilities from $X_n = i$ to $X_{n+1} = j$ depend on $j-i$ only and not specifically on i and j (for i and j greater than or equal to 1).

Similarly to the discrete case, a continuous-time Markov process on the state space E with a generator matrix Q having the same block structure as P in Equation (1) is called a *continuous-time M/G/1-type* Markov process.

By using the uniformization technique [4, Section 2.8], one can easily transform the

continuous-time process defined by Q into a discrete-time M/G/1-type Markov chain with transition matrix $P = \frac{1}{c}Q + I$, where c is such that $c \geq |q_{i,i}|$, for any i , where $q_{i,i}$ are the diagonal entries of Q . In this way, theory and algorithms valid for discrete-time M/G/1-type Markov chains can be applied to the case of continuous-time Markov chains.

Throughout the article, we denote by $\mathbf{1}$ a vector with all components equal to 1 whose dimension is determined by the context.

An Example

A simple example of an M/G/1-type Markov chain comes from the model of a buffer in a telecommunications system [3]. The buffer content follows the evolution equation

$$X_{n+1} = \max(X_n + \alpha_n - 1, 0),$$

where X_n is the buffer occupancy at time n and α_n is the number of new packets that arrive during the n th transmission interval. We assume that the packet lengths are fixed and have a length of one time slot. The α_n 's depend on various factors such as the number of active customers or the congestion of the network. These external factors often are modeled as a Markov chain $\{\varphi_n\}$ on some state space S_m , and one lets the distribution of α_n depend on φ_n .

Under this assumption, the two-dimensional process $\{(X_n, \varphi_n)\}$ is a Markov chain on the state space $E = \mathbb{N} \times S$ with the transition matrix P of Equation (1), where $B_i = A_i$, $i \geq 1$, $C = A_{-1}$, $B_0 = A_{-1} + A_0$, with

$$(A_k)_{i,j} = P[\alpha_n = k+1, \varphi_{n+1}=j | \varphi_n=i] \\ \text{for } k \geq -1, i, j \in S_m,$$

being the probability that $k+1$ packets arrive during a packet transmission interval, and that the next phase is j , given that the current one is i .

A detailed analysis of other examples of this paradigm can be found in Refs 5 and 6.

Non-Skip-Free Markov Chains

A generalization that falls in the class of M/G/1-type Markov chains is the class of non-skip-free M/G/1-type Markov chains where

the number of boundary levels is $N \geq 1$. In this case, the transition matrix is given by

$$P = \begin{bmatrix} B_{0,0} & B_{0,1} & B_{0,2} & \dots \\ B_{1,0} & B_{1,1} & B_{1,2} & \dots \\ \vdots & \vdots & \vdots & \vdots \\ B_{N-1,0} & B_{N-1,1} & B_{N-1,2} & \dots \\ A_{-N} & A_{-N+1} & A_{-N+2} & \dots \\ & A_{-N} & A_{-N+1} & \ddots \\ & & A_{-N} & \ddots \\ 0 & & & \ddots \end{bmatrix},$$

where the blocks $B_{i,j}$ and A_i have size $m \times m$. We may view this matrix as having the structure (Eq. 1) with blocks of size Nm , corresponding to what we might call “macro levels”:

$$P = \begin{bmatrix} B_0 & B_1 & B_2 & \dots \\ A_{-1} & A_0 & A_1 & \dots \\ & A_{-1} & A_0 & \ddots \\ 0 & & \ddots & \ddots \end{bmatrix},$$

where

$$A_i = \begin{bmatrix} A_{iN} & A_{iN+1} & \dots & A_{iN+N-1} \\ A_{iN-1} & A_{iN} & \ddots & \vdots \\ \vdots & \ddots & \ddots & A_{iN+1} \\ A_{iN-N+1} & \dots & A_{iN-1} & A_{iN} \end{bmatrix},$$

for $i = -1, 0, 1, \dots$, where we assume that $A_j = 0$ if $j < -N$, and

$$B_i = \begin{bmatrix} B_{0,Ni} & B_{0,Ni+1} & \dots & B_{0,Ni+N-1} \\ B_{1,Ni} & B_{1,Ni+1} & \dots & B_{1,Ni+N-1} \\ \vdots & \vdots & \ddots & \vdots \\ B_{N-1,Ni} & B_{N-1,Ni+1} & \dots & B_{N-1,Ni+N-1} \end{bmatrix},$$

$i \geq 0$.

An instance of a non-skip-free Markov chain is given by an M/G/1 model with batch services where at most a batch of size $N < +\infty$ is taken into service with probability p_k for a batch of size k .

Assumptions

The following assumptions on the M/G/1-type Markov chain with transition matrix (Eq. 1) will be useful.

Condition 1. The Markov chain with transition matrix (Eq. 1) is irreducible and aperiodic.

Condition 2. In addition to being stochastic, the following matrix is irreducible:

$$A = \sum_{i=-1}^{+\infty} A_i.$$

The above assumption is not restrictive. In fact, if A is reducible, it is possible to consider A in its reduced form. This way, the problem can be split into a set of smaller irreducible problems. Details on this strategy can be found in Section 3.5 of Ref. 1 and in Refs 7, 8.

Consider the Markov chain defined on the set of states $\mathbb{Z} \times S_m$, where $\mathbb{Z}$ is the set of all integers, with transition matrix

$$P' = \begin{bmatrix} \ddots & \ddots & \ddots & \ddots & \ddots & \ddots \\ \ddots & A_0 & A_1 & A_2 & A_3 & \ddots \\ & A_{-1} & A_0 & A_1 & A_2 & \ddots \\ & & A_{-1} & A_0 & A_1 & \ddots \\ & & & A_{-1} & A_0 & \ddots \\ 0 & & & & \ddots & \ddots \end{bmatrix}; \quad (2)$$

that is, we remove the boundary at level 0 and allow the Markov chain to move freely to any negative level, as well as to the positive ones.

Condition 3. The Markov chain on $\mathbb{Z} \times S_m$ with transition matrix (Eq. 2) has only one final class $\mathbb{Z} \times S$, where $S \subseteq S_m$. Every other state is on a path to the final class.

A final class is a set of states S such that there is no path going out of S , and for any pair of states $i, j \in S$ there is a path connecting i to j . We refer the reader to Ref. 3 (Chapter 4) for a discussion on the above assumptions.

POSITIVE RECURRENCE

The peculiar structure of the matrix P enables one to provide simple conditions for the positive recurrence of the Markov chain. For Markov chains, recurrence properties are governed by almost sure returns to the states, and for M/G/1-type chains, studying returns involves considering the first entrance to lower level states.

Here and hereafter we assume that Condition 1 holds.

Assume that $C = A_{-1}$ and define θ as the first return time to the level 0:

$$\theta = \min\{n \geq 0 : X_n = 0\}$$

and consider the matrix $G = (G_{j,j'})$, with entries

$$G_{j,j'} = P[\theta < \infty, \varphi_\theta = j' | X_0 = 1, \varphi_0 = j]$$

being the probability that, starting from the state $(1, j)$ in level 1, the process reaches down to the level 0 in a finite time, and that $(0, j')$ is the first state visited in level 0.

Observe that [3] the matrix G is the matrix of first passage probabilities from level $k + 1$ to level k , independently of $k \geq 0$. The matrix G is strictly related to the matrix equation

$$X = \sum_{i=-1}^{+\infty} A_i X^{i+1}, \quad (3)$$

where the unknown X is an $m \times m$ matrix, as stated by the following result [3, Theorem 4.3]:

Theorem 1. *The matrix G is the minimal nonnegative solution of Equation (3), that is, G satisfies Equation (3) and $G \leq Y$ for any other nonnegative solution Y of Equation (3). If the Markov chain is recurrent, then G is stochastic; otherwise, it is substochastic with $G\mathbf{1} \leq \mathbf{1}$, $G\mathbf{1} \neq \mathbf{1}$.*

The following result [3, Theorem 4.7] gives the necessary and sufficient conditions for positive recurrence:

Theorem 2. *Assume that Conditions 1 and 2 hold and that $\sum_{i=-1}^{+\infty} (i+1)A_i < +\infty$, so*

that we may define the vector $\mathbf{a} = \sum_{i=-1}^{+\infty} iA_i\mathbf{1}$; moreover, set

$$\mu = \boldsymbol{\alpha}^T \mathbf{a}, \quad (4)$$

where $\boldsymbol{\alpha}$ is the vector such that $\boldsymbol{\alpha}^T A = \boldsymbol{\alpha}^T$, $\boldsymbol{\alpha}^T \mathbf{1} = 1$, for $A = \sum_{i=-1}^{+\infty} A_i$. Then the Markov chain with transition matrix (Eq. 1) is recurrent if and only if $\mu \leq 0$ and transient if and only if $\mu > 0$. It is positive recurrent if and only if $\mu < 0$ and $\mathbf{b} = \sum_{i=1}^{+\infty} iB_i\mathbf{1} < \infty$.

For the proof of the above result we refer the reader to Ref. 9, Proposition 4.6, Ref. 1, Theorem 1.3.1, or Ref. 10, Corollary 3. Theorem 2 is simple to interpret. Assume that the state is (n, i) at some time t ; at time $t + 1$, it will be (n', j) , with n' and j random. The component a_i of the vector $\mathbf{a}$ is the expectation of the jump size $n' - n$, when the phase is i , and μ is obtained by averaging over the phases with the probability distribution $\boldsymbol{\alpha}$. If $\mu < 0$, then the jumps are negative on average and the process is attracted to the level 0 at the bottom of the state space. The number μ defined in Equation (4) is called *drift* of the Markov chain.

Conditions for positive recurrence can be given also in terms of the location of the zeros of the function $a(z) = \det(zI - A(z))$, as proved in Ref. 10 (see also Ref. 3, Theorem 4.9).

Theorem 3. *Assume that Condition 2 holds, and that $\mathbf{a}$ is finite. Define*

$$\kappa = \max\{k : z^{-m/k} a(z^{1/k}) \text{ is a (single valued) function in } |z| \leq 1\}.$$

Then the following properties hold:

- *if $\mu < 0$, then $a(z)$ has $m - \kappa$ zeros in the open unit disk, and κ simple zeros on the unit circle at the κ th roots of 1;*
- *if $\mu = 0$ and $\sum_{i=-1}^{+\infty} (i+1)^2 A_i$ is finite, then $a(z)$ has $m - \kappa$ zeros in the open unit disk, and κ zeros of multiplicity 2 on the unit circle at the κ th roots of 1;*
- *if $\mu > 0$, then $a(z)$ has m zeros in the open unit disk, and κ simple zeros on the unit circle at the κ th roots of 1.*

The eigenvalues of G are a special subset of the zeros of $a(z)$, as shown in Ref. 11 (see also 3, Theorem 4.10)

Theorem 4. *Under the hypotheses of Theorem 3 the eigenvalues of G are:*

- the zeros of $a(z)$ in the closed unit disk if $\mu < 0$;
- the zeros of $a(z)$ in the open unit disk and the κ th roots of 1 if $\mu = 0$;
- the zeros of $a(z)$ in the open unit disk if $\mu > 0$.

Observe that, if $G\mathbf{u} = \lambda\mathbf{u}$, then $(\lambda I - A(\lambda))\mathbf{u} = 0$. If λ is the spectral radius of G , then under Condition 2 there exists a positive vector $\mathbf{u}$ such that $G\mathbf{u} = \lambda\mathbf{u}$ (see Ref. 1, Lemma 2.3.1).

Reducing Transient to Positive Recurrent Markov Chains

In developing the theory, it is customary to restrict oneself to positive recurrent Markov chains. An extension to the transient case is enabled by the following result which shows that, to any transient Markov chain of the M/G/1-type, one can associate a closely related chain that is positive recurrent.

More precisely, the following property derives from the results of Refs 12–14.

Theorem 5. *Assume that Condition 2 holds and that the Markov chain with transition matrix (Eq. 1) is transient. Let ξ be the spectral radius of G , and $\mathbf{u} = (u_i)$ a positive vector such that $G\mathbf{u} = \xi\mathbf{u}$ where G is the minimal nonnegative solution of Equation (3). Define the following matrices*

$$C_i = \xi^i D^{-1} A_i D, \quad i = -1, 0, 1, 2, \dots,$$

for $D = \text{Diag}(\mathbf{u})$ being the diagonal matrix with diagonal entries $u_1, u_2, \dots, u_m$. Then C_i are nonnegative matrices such that $\sum_{i=-1}^{+\infty} C_i$ is stochastic, $H = \xi^{-1} D^{-1} G D$ is the minimal nonnegative solution of the matrix equation

$$X = \sum_{i=-1}^{+\infty} C_i X^{i+1},$$

and the spectral radius of H is 1. Moreover, the Markov chain defined by the transition matrix P of Equation (1) where the blocks A_i are replaced with the blocks C_i , is positive recurrent if $\sum_{i=1}^{+\infty} i B_i$ is finite.

From GI/M/1 to M/G/1

Another major structural class of Markov chains besides the M/G/1-type is the set of Markov chains of the GI/M/1-type. There exists a set of duality results [15] that allow GI/M/1-type chains to be studied in terms of closely related M/G/1-type chains. These results are useful algorithmically also in that certain key quantities like the R matrix (see Refs 3, 16, 17) can be directly expressed in terms of the better behaved G matrix of the associated M/G/1-type chain.

Let

$$P = \begin{bmatrix} B_0 & A_1 & & & 0 \\ B_{-1} & A_0 & A_1 & & \\ B_{-2} & A_{-1} & A_0 & A_1 & \\ B_{-3} & A_{-2} & A_{-1} & A_0 & \ddots \\ \vdots & \vdots & \ddots & \ddots & \ddots \end{bmatrix} \quad (5)$$

be the transition matrix of a GI/M/1-type Markov chain, where we assume that $\sum_{i=-1}^{+\infty} A_{-i}$ is irreducible and stochastic.

Let R be the minimal nonnegative solution of the matrix equation

$$X = \sum_{i=-1}^{+\infty} X^{i+1} A_{-i}.$$

Define $D = \text{diag}(\boldsymbol{\alpha})$, where $\boldsymbol{\alpha}$ is the strictly positive stationary probability vector of A and define $\tilde{A}_i = D^{-1} A_{-i}^T D$, for $i = -1, 0, 1, \dots$. Note that the matrix $\tilde{A} = \sum_{i=-1}^{+\infty} \tilde{A}_i$ is stochastic and has the same stationary probability vector $\boldsymbol{\alpha}$ as A . Then $G = D^{-1} R^T D$ is the minimal nonnegative solution of

$$X = \sum_{i=-1}^{+\infty} \tilde{A}_i X^{i+1}, \quad (6)$$

which is the characteristic equation of the M/G/1-type Markov chain with

transition matrix

$$P = \begin{bmatrix} \tilde{B}_0 & \tilde{B}_1 & \tilde{B}_2 & \tilde{B}_3 & \dots \\ \tilde{A}_{-1} & \tilde{A}_0 & \tilde{A}_1 & \tilde{A}_2 & \dots \\ & \tilde{A}_{-1} & \tilde{A}_0 & \tilde{A}_1 & \ddots \\ & & \tilde{A}_{-1} & \tilde{A}_0 & \ddots \\ 0 & & & \ddots & \ddots \end{bmatrix}, \quad (7)$$

where $\tilde{B}_i = D^{-1}B_{-i}^T D$, for $i = 0, 1, 2, \dots$. Furthermore, it is easy to see that the drift $\tilde{\mu} = \alpha^T \sum_{i=-1}^{+\infty} (i+1)\tilde{A}_i \mathbf{1}$ of the new Markov chain is equal to the drift δ of the Markov chain (5). In this way, a positive recurrent (transient) GI/M/1-type Markov chain is equivalent to a transient (positive recurrent) M/G/1-type Markov chain.

STEADY-STATE VECTOR

Throughout this section, we assume that Conditions 1 and 2 hold and that the Markov chain with transition matrix (Eq. 1) is positive recurrent. We denote by $\pi \in \mathbb{R}^N$ the stationary probability vector, that is, the unique solution of the system

$$\pi^T = \pi^T P, \quad \pi^T \mathbf{1} = 1,$$

and we partition it as $\pi = (\pi_n)_{n=0,1,\dots}$, with $\pi_0 = (\pi_{0,j})_{j=1,\dots,m_0}$, $\pi_n = (\pi_{n,j})_{j=1,\dots,m}$, $n \geq 1$, and $\pi_{n,j} = \lim_{t \rightarrow +\infty} P[X_t = n, \varphi_t = j | X_0 = n', \varphi_0 = j']$, independently of n' and j' .

The next theorem gives a recursive expression for the steady-state vector, known as *Ramaswami's formula*. This formula has been proved for the first time in Ref. 18 (see also Refs 1, Theorem 3.2.5 and 3, Theorem 4.4) by using probabilistic arguments, and interpreted in terms of algebraic properties in Refs 19 and 20 (see also 3, Section 4.5)

Theorem 6. *Let*

$$\begin{aligned} A_n^* &= \sum_{i=n}^{+\infty} A_i G^{i-n}, \\ B_n^* &= \sum_{i=n}^{+\infty} B_i G^{i-n}, \quad \text{for } n \geq 0. \end{aligned} \quad (8)$$

Then $I - A_0^*$ is nonsingular,

$$\begin{aligned} \pi_n^T &= \left(\pi_0^T B_n^* + \sum_{i=1}^{n-1} \pi_i^T A_{n-i}^* \right) (I - A_0^*)^{-1}, \\ &\text{for } n \geq 1, \end{aligned} \quad (9)$$

and π_0 is the unique solution of the system

$$\begin{aligned} \pi_0^T B_0^* &= \pi_0^T, \\ \pi_0^T \mathbf{b} - \mu \pi_0^T \mathbf{1} + \pi_0^T (I - B) W \mathbf{a} &= -\mu, \end{aligned}$$

where $B = \sum_{n=0}^{+\infty} B_n$ and $W = (I - A + \mathbf{1} \mathbf{a}^T)^{-1} - \mathbf{e} \mathbf{a}^T$.

The following result [3, Theorem 4.13], relating the generating functions of the sequences $\{A_i\}$ and $\{A_i^*\}$, is the basis of the algebraic interpretation of Ramaswami's formula:

Theorem 7. *Under the hypotheses of Theorem 3, the Laurent matrix power series $I - S(z)$, $S(z) = \sum_{i=-1}^{+\infty} z^i A_i$, has the following factorization*

$$\begin{aligned} I - S(z) &= U(z) L(z), \quad |z| = 1, \\ U(z) &= I - \sum_{i=0}^{+\infty} z^i A_i^*, \quad L(z) = I - z^{-1} G, \end{aligned}$$

where A_i^* , for $i \geq 0$, are defined in Equation (8). Moreover,

- if $\mu < 0$ then $U(z)$ is nonsingular for $|z| = 1$, $L(z)$ is singular for $z = \omega_\kappa^i$, $i = 0, \dots, \kappa - 1$, and the coefficients of $L(z)^{-1}$ are uniformly bounded in norm by a constant;
- if $\mu = 0$ and $\sum_{i=-1}^{+\infty} (i+1)^2 A_i$ is finite, then both $L(z)$ and $U(z)$ are singular for $z = \omega_\kappa^i$, $i = 0, \dots, \kappa - 1$ and the coefficients of $L(z)^{-1}$ are uniformly bounded in norm by a constant;
- if $\mu > 0$ then $L(z)$ is nonsingular for $|z| = 1$, $U(z)$ is singular for $z = \omega_\kappa^i$, $i = 0, \dots, \kappa - 1$.

Qualitative properties of π , like the exponential decay of its components, have been proved in Refs 21 and 22.

TRANSFORMATION INTO QBD

An M/G/1-type Markov chain can be transformed into a suitable QBD process having an infinite number of phases as shown in Ref. 23. For notational simplicity, we assume that $m_0 = m$.

In the transition matrix (Eq. 1), we replace the simple transitions of the form $(n, i) \rightarrow (n + k, j)$ by a more elaborate virtual procedure, whereby a new phase j is chosen first, as well as a number k of steps upward, and only then the level is increased, one unit at a time, until level $n + k$ is finally reached. Graphically, we have

$$\begin{aligned} (n, i) &\rightarrow (n; k, j) \rightarrow (n + 1; k - 1, j) \cdots \\ &\rightarrow (n + k - 1; 1, j) \rightarrow (n + k, j). \end{aligned}$$

At each transition of this virtual sequence, one keeps track of the number of steps that remain until the final level is reached. In order to have homogeneous notation, we shall write (n, i) as $(n; 0, i)$.

We define in this way a three-dimensional process $\{X_t, K_t, \varphi_t\}_{t=0,1,\dots}$ on the state space $\mathbb{N} \times \mathbb{N} \times S_m$ for which the pair (K_t, φ_t) constitutes the phase. We also write that K_t is the *sublevel*. The transition matrix of the new process is

$$P = \begin{bmatrix} \mathcal{B} & \mathcal{A}_1 & & 0 \\ \mathcal{A}_{-1} & \mathcal{A}_0 & \mathcal{A}_1 & \\ & \mathcal{A}_{-1} & \mathcal{A}_0 & \ddots \\ 0 & & \ddots & \ddots \end{bmatrix}, \quad (10)$$

with

$$\begin{aligned} \mathcal{A}_{-1} &= \begin{bmatrix} \mathcal{A}_{-1} & 0 & \cdots \\ 0 & 0 & \cdots \\ \vdots & \vdots & \ddots \end{bmatrix}, \\ \mathcal{A}_0 &= \begin{bmatrix} \mathcal{A}_0 & \mathcal{A}_1 & \cdots \\ 0 & 0 & \cdots \\ \vdots & \vdots & \ddots \end{bmatrix}, \\ \mathcal{A}_1 &= \begin{bmatrix} 0 & 0 \\ I & 0 \\ & I & \ddots \\ 0 & & \ddots \end{bmatrix}, \end{aligned}$$

and

$$\mathcal{B} = \begin{bmatrix} B_0 & B_1 & \cdots \\ 0 & 0 & \cdots \\ \vdots & \vdots & \ddots \end{bmatrix},$$

The following result relates the QBD 10 to the M/G/1-type Markov chain 1 (see Ref. 3, Theorem 5.21).

Theorem 8. *The minimal nonnegative solution $\mathcal{G}$ of the matrix equation*

$$\mathcal{X} = \mathcal{A}_{-1} + \mathcal{A}_0 \mathcal{X} + \mathcal{A}_1 \mathcal{X}^2$$

associated with the QBD (Eq. 10) is

$$\mathcal{G} = \begin{bmatrix} G & 0 & 0 & \cdots \\ G^2 & 0 & 0 & \cdots \\ G^3 & 0 & 0 & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix}.$$

NUMERICAL METHODS

Once the minimal nonnegative solution G to the matrix equation (3) has been computed, the invariant probability vector of an M/G/1-type Markov chain can be obtained by means of formula (9).

In certain applications, the blocks A_i may have some special structure which is inherited by G . A meaningful case is when $\mathcal{A}_{-1}$ is a rank-one matrix, that is, $\mathcal{A}_{-1} = \mathbf{u}\mathbf{v}^T$ for some vectors $\mathbf{u}, \mathbf{v}$ [8,7]. It is possible to prove that in the positive recurrent case $G = \frac{1}{v^T \mathbf{1}} \mathbf{1}\mathbf{v}^T$, that is G has rank one. In general, an explicit formula for G cannot be given and numerical methods for its computation must be provided.

Therefore in this section we focus our attention on the computation of G .

Fixed-Point Iterations

In this section, we report results concerning the approximation of the minimal nonnegative solution of Equation (3) by means of fixed-point iterations. For more details, we refer the reader to Ref. 3, Chapter 6 and to Refs 24–28.

A natural way for generating a matrix sequence converging to a solution of Equation

(3) is given by the following fixed-point iteration known in the literature as *natural iteration*:

$$X_{k+1} = \sum_{i=-1}^{+\infty} A_i X_k^{i+1}, \quad k = 0, 1, \dots \quad (11)$$

starting from a given initial approximation X_0 .

Indeed, if the sequence $\{X_k\}$ has a limit X^* , then X^* is a solution of Equation (3).

By rewriting the original Equation (3) in the form

$$X = (I - A_0)^{-1} \left(A_{-1} + \sum_{i=1}^{+\infty} A_i X^{i+1} \right),$$

one obtains the so-called *traditional iteration*

$$X_{k+1} = (I - A_0)^{-1} \left(A_{-1} + \sum_{i=1}^{+\infty} A_i X_k^{i+1} \right), \quad k = 0, 1, \dots \quad (12)$$

In a similar way, one obtains the iteration

$$X_{k+1} = \left(I - \sum_{i=0}^{+\infty} A_i X_k^i \right)^{-1} A_{-1}, \quad k = 0, 1, \dots, \quad (13)$$

which is known as *U-based iteration*. The name is motivated by the fact that the matrix $\sum_{i=0}^{+\infty} A_i G^i$, which appears in the right-hand side of Equation (13) with $X_k = G$, is customarily denoted by U .

The following convergence results hold:

Theorem 9. *For $X_0 = 0$ the iterations (11), (12), (13), converge monotonically to G . Denoting X_k^N , X_k^T and X_k^U the sequences generated by the natural, traditional and U-based iterations, respectively, it holds*

$$X_k^N \leq X_k^T \leq X_k^U,$$

where the inequalities are meant component-wise. If $X_0 = I$, the sequences generated by the iterations (11), (12), (13), converge to a stochastic solution G^* of Equation (3). In the recurrent case $G^* = G$.

It has been proved in Ref. 28 that in the recurrent case each one of the three sequences generated with $X_0 = I$ converges to G faster than the corresponding sequence obtained with $X_0 = 0$. That is, the error reduction per step is larger for $X_0 = I$.

The iterations based on Equations (11), (12), and (13) have a linear convergence in the transient or in the positive recurrent case. That is, for any norm there exists, independent of the norm, the limit $\limsup_k \|G - X_k\|^{1/k} = \theta$, and $0 < \theta < 1$ holds. In other words, the error $\|G - X_k\|$ converges to zero exponentially as θ^k . In the null-recurrent case with $X_0 = 0$, it holds $\theta = 1$, which means that the error $\|G - X_k\|$ does not tend to zero exponentially and convergence slows down much. This kind of convergence is called *sublinear*.

A quadratically convergent iteration, that is, such that $\limsup_k \|G - X_k\|^{1/2^k} < 1$, can be obtained by applying Newton's method to the equation

$$X - \left(I - \sum_{i=0}^{+\infty} A_i X^i \right) A_{-1} = 0,$$

which generates the sequence

$$X_{k+1} = X_k - H_k, \quad k = 0, 1, 2, \dots, \quad (14)$$

where H_k solves the linear matrix equation in the unknown H

$$\begin{aligned} H - U_k \left(\sum_{i=1}^{+\infty} A_i \right) \left(\sum_{j=0}^{i-1} X_k^j H X_k^{i-1-j} \right) U_k A_{-1} \\ = X_k - U_k A_{-1}, \quad U_k = \left(I - \sum_{i=0}^{+\infty} A_i X_k^i \right)^{-1}. \end{aligned}$$

More details on this method can be found in Refs 24, 27, 29.

In the positive recurrent case, if $0 \leq X_0 \leq G$, then the sequence X_k generated by 14 converges monotonically to G with quadratic convergence speed.

Even though the speed of convergence is higher, the cost of a single step of Newton's iteration is much larger than the cost of a single step of one of the three iterations (11), (12), and (13). This is due to the large cost needed for computing the matrix H_k .

Doubling Methods

Doubling methods have the nice feature to provide the quadratic convergence speed while still maintaining a low cost per step.

Cyclic reduction (CR) is one of the most efficient doubling algorithms. It is based on a technique introduced in the 1970s by Hockney [30] and Buzbee *et al.* [31] for solving special linear systems and specialized to M/G/1-type Markov chains in Refs 3, Chapter 7, 12, 32, 33. In the context of Markov chains, the idea on which CR is based is to divide the set of levels into two groups: the ones with odd indices and the ones with even indices, and to apply censoring. The new Markov chain obtained in this way is still of the M/G/1-type so that the process can be applied cyclically. CR can be viewed as an extension to M/G/1-type Markov chains of the logarithmic reduction algorithm by Latouche and Ramaswami [34], designed for the solution of QBDs. Comparisons and relationships between CR and logarithmic reduction can be found in Refs 3, Chapter 7, 12, 35.

A natural way for rigorously describing CR is to introduce the matrix power series $A(z) = \sum_{i=-1}^{+\infty} z^{i+1} A_i$. Starting from $A^{(0)}(z) = A(z)$ and $\hat{A}^{(0)}(z) = \sum_{i=0}^{+\infty} z^i A_i$, CR generates the following two sequences of matrix power series $A^{(n)}(z) = \sum_{i=-1}^{+\infty} z^{i+1} A_i^{(n)}$, and $\hat{A}^{(n)}(z) = \sum_{i=0}^{+\infty} z^i \hat{A}_i^{(n)}$ recursively defined by

$$\begin{aligned} A^{(n+1)}(z) &= z A_{\text{odd}}^{(n)}(z) + A_{\text{even}}^{(n)}(z) (I \\ &\quad - A_{\text{odd}}^{(n)}(z))^{-1} A_{\text{even}}^{(n)}(z), \\ \hat{A}^{(n+1)}(z) &= \hat{A}_{\text{even}}^{(n)}(z) + \hat{A}_{\text{odd}}^{(n)}(z) (I \\ &\quad - A_{\text{odd}}^{(n)}(z))^{-1} A_{\text{even}}^{(n)}(z), \end{aligned} \quad (15)$$

where for a generic matrix power series $F(z) = \sum_{i=0}^{+\infty} z^i F_i$ we define

$$\begin{aligned} F_{\text{even}}(z) &= \frac{1}{2} (F(\sqrt{z}) + F(-\sqrt{z})) = \sum_{i=0}^{+\infty} z^i F_{2i}, \\ F_{\text{odd}}(z) &= \frac{1}{2\sqrt{z}} (F(\sqrt{z}) - F(-\sqrt{z})) = \sum_{i=0}^{+\infty} z^i F_{2i+1}. \end{aligned}$$

We have the following properties [3]:

Theorem 10. *Assume that Conditions 1 and 3 hold. Moreover, if the Markov chain*

with transition matrix (Eq. 1) is positive recurrent assume also that $A(z)$ is analytic in a disk of radius greater than 1 and that there exists a zero of $a(z) = \det(zI - A(z))$ of modulus greater than 1. If the Markov chain is positive recurrent or transient, then for the matrix power series $A^{(n)}(z)$ and $\hat{A}^{(n)}(z)$ generated by CR one has:

1. *the matrices $A_i^{(n)}$, $\hat{A}_{i+1}^{(n)}$, $i = -1, 0, 1, \dots$, are nonnegative and such that $A^{(n)}(1)$, $A_{-1} + \hat{A}^{(n)}(1)$ are stochastic;*
2. *the matrices $I - \hat{A}_0^{(n)}$ are nonsingular for $n = 0, 1, 2, \dots$ and such that*

$$G = (I - \hat{A}_0^{(n)})^{-1} \times \left(A_{-1} + \sum_{i=1}^{+\infty} \hat{A}_i^{(n)} G^{i \cdot 2^n + 1} \right);$$

3. *for any matrix norm $\|\cdot\|$ there exists a constant γ such that*

$$\begin{aligned} \|G - G_n\| &\leq \gamma \sigma^{-2^n}, \\ G_n &= (I - \hat{A}_0^{(n)})^{-1} A_{-1} \end{aligned}$$

for any σ such that $1 < \sigma < \xi$, where in the positive recurrent case ξ is the smallest real number greater than 1 such that $a(\xi) = 0$, while in the transient case $\xi = \theta^{-1}$ with θ being the largest real number less than 1 such that $a(\xi) = 0$.

The convergence of G_n to G described in part 3 of the above theorem is said to be quadratic with rate ξ^{-1} . In the case of null-recurrent Markov chains, part 1 of the above theorem still holds but convergence turns linear.

If the M/G/1-type Markov chain reduces to a QBD then the cyclic reduction step can be implemented by means of a few matrix operations without involving matrix power series. In this case, CR shares common properties with the algorithm of logarithmic reduction of Ref. 34.

For general M/G/1-type Markov chains, the functional formulation (15) of CR enables one to provide an effective implementation of each step by means of the evaluation/interpolation technique at the

set of Fourier points. More details on this algorithm can be found in Refs 3, Chapter 7 and 33. With this technique, the matrix power series are numerically approximated by matrix polynomials, and fast polynomial arithmetic based on the fast Fourier transform (FFT) is applied. Owing to the quadratic convergence, the matrix power series generated at the generic step n of CR are well approximated by polynomials whose degree decreases to zero in a few steps.

A different implementation, given in matrix form, but still based on FFT, can be found in Ref. 32. Advanced software implementing CR and other effective algorithms can be found in Refs 36 and 37.

An alternative approach is to apply CR to the QBD process obtained by means of the transformation described in the section titled "Transformation into QBD." Indeed, as already pointed out, applying CR to a QBD does not require the matrix power series machinery; on the other hand, managing with blocks of infinite size makes the implementation of the CR step more tricky. A discussion on this approach can be found in Refs 3, Section 9.3 and 38.

A different doubling method, described in Refs 39 and 40 and improved in Refs 3 and 41, is based on the successive solution of the sequence of block Hessenberg systems

$$\begin{bmatrix} I - A_0 & -A_1 & \dots & -A_{n-1} \\ -A_{-1} & I - A_0 & \ddots & \vdots \\ & \ddots & \ddots & -A_1 \\ 0 & & -A_{-1} & I - A_0 \end{bmatrix} \begin{bmatrix} X_1^{(n)} \\ X_2^{(n)} \\ \vdots \\ X_n^{(n)} \end{bmatrix} = \begin{bmatrix} A_{-1} \\ 0 \\ \vdots \\ 0 \end{bmatrix}. \quad (16)$$

Indeed, it is possible to prove that for any norm $\|\cdot\|$ there exists a constant $\gamma > 0$ such that

$$\|G - X_1^{(n)}\| \leq \gamma \sigma^{-n}$$

for any σ such that $1 < \sigma < \xi$, where ξ is defined in Theorem 10.

The computation of $X_1^{(n)}$ can be performed by means of a doubling technique by solving the system (Eq. 16) for $n = 2^k$, with $k = 1, 2, \dots$. In fact, the solution of Equation (16) with $n = 2^k$ can be easily computed from the solution of Equation (16) with $n = 2^{k-1}$. The numerical performances of this technique are generally inferior to those of CR.

Other doubling methods, based on the computation of an invariant subspace of a suitable matrix, have been introduced in Ref. 42. These algorithms are quadratically convergent but may suffer from numerical instabilities. The reader can find more details on this class of algorithms in Refs 3 [Section 8.6], 35, 43.

Acceleration Techniques

In the case of null-recurrent and close to null-recurrent Markov chains, the convergence speed of the algorithms described in the previous sections slows down significantly. A way to overcome this drawback is to apply the *shift technique* introduced in Ref. 44 and improved in Ref. 45.

The idea is to replace the original matrix equation with a new one

$$X = \sum_{i=-1}^{+\infty} \tilde{A}_i X^{i+1} \quad (17)$$

for suitable matrices $\tilde{A}_i$ such that the convergence of iterative methods of the previous two sections applied to the new equation is faster and the solution of the original matrix equation can be easily computed from the solution of the new one.

More precisely, we have the following result [3, Theorems 3.32, 3.33].

Theorem 11. *Assume that the Markov chain defined by the transition matrix (Eq. 1) is recurrent. Let $\mathbf{u}$ be any vector such that $\mathbf{u}^T \mathbf{e} = 1$ and define $\tilde{A}_{-1} = A_{-1} - A_{-1}Q$, $\tilde{A}_i = A_i + (I - \sum_{j=-1}^i A_j)Q$, $i = 0, 1, \dots$, with $Q = \mathbf{1u}^T$. Then the matrix equation (17) has a unique solution $\tilde{G}$ with spectral radius less than 1. Moreover, it holds $G = \tilde{G} + Q$.*

It is possible to prove that cyclic reduction as well as the doubling method based

on Equation (16) applied to Equation (17) converges quadratically with rate η/ξ , for a suitable $0 < \eta < 1$, in the positive recurrent case, and with rate $1/\xi$ in the null-recurrent case.

Also, the fixed-point iterations applied to the new Equation (17) increase their convergence.

Sometimes it is useful to shift more than one eigenvalue. The technique obtained in this way is known as *multiple shift*.

Software

Some software packages have been designed containing the implementation of the most effective methods for solving M/G/1-type Markov chains. A Matlab Toolbox called *SMCSolver* [36,37], is available at Ref. 46. It covers M/G/1-type, GI/M/1-type, QBD, and non-skip-free Markov chains. A Fortran version with a graphical interface is available at Ref. 47.

This tool computes the matrix G (or R) of M/G/1-type, GI/M/1-type, and non-skip-free Markov chains as well as its steady-state probability vector. It includes implementations of the following algorithms: cyclic reduction, fixed-point iterations, invariant subspace, and Ramaswami reduction to a QBD. The steady-state vector is computed by means of the Ramaswami formula.

Another Matlab Toolbox, called *Q-MAM*, is based on *SMCSolver* and available at [46]. It performs further computations like the queue length, waiting time, and delay distribution of various queueing systems of infinite size. It includes, amongst others, implementations of the following queueing models both in discrete and continuous-time: PH/PH/1, MAP/MAP/1, MAP/M/c, MAP/D/c, RAP/RAP/1, MMAP[K]/PH[K]/1, and others.

Another package, called *MAMSolver* and available at Ref. 48, provides solutions for both continuous- and discrete-time Markov chains of QBD, GI/M/1, and M/G/1-types. It relies on the Matlab version of *SMCSolver*, computes the matrix G by means of cyclic reduction and logarithmic reduction, and uses an alternate algorithm to the Ramaswami formula called *ETAQA* [49] for computing π .

FURTHER READING

There is a vast literature concerning M/G/1-type Markov chains and the algorithms for their solution. The pioneering monograph of M.F. Neuts [1] provides an important reference in this regard.

Two interesting (even though not recent) surveys are Refs 50 and 51. The book [4], even though concerning QBDs, contains basic definitions and properties of M/G/1-type Markov chains. An interesting tutorial that gives the Markov renewal framework and extends the theory to the infinite-dimensional case is Ref. 52.

Important collections of theoretical results, algorithm, and applications can be found in the proceedings of a series of conferences called *Matrix Analytic Methods in Stochastic Models* [53–58]. Other interesting sources of results are the Proceedings of the Dagstuhl Seminar “Numerical Methods for Structured Markov Chains” [59] and the special issue of *Stochastic Models* [60] in honor of M.F. Neuts. Algorithmic issues are developed in the book [3], and a more probabilistic oriented approach can be found in the book [61].

MARKOV REGENERATIVE PROCESSES

YASEMIN SERIN
Industrial Engineering Department,
Middle East Technical University,
Ankara, Turkey

INTRODUCTION

Markov regenerative processes (MRGPs) are continuous-time stochastic processes with more general conditions of regeneration than regenerative processes. Some authors refer to these processes as *semi-regenerative processes* [1]. The limiting lengths of some queues with general distributions can be obtained using the results related to MRGPs. This article benefitted from Çinlar [1] and is largely based on Kulkarni [2]. The proofs of the theorems below can be found in Kulkarni [2].

DEFINITIONS AND TRANSIENT BEHAVIOR

A Markov renewal sequence (MRS) is a generalization of a renewal sequence and a MRGP is a generalization of a regenerative process. The first is a discrete-time process and the second is a continuous-time process; in both the future depends on the past only through the state at the last “regeneration.”

Definition. The process $\{(X_n, S_n), n = 0, 1, 2, \dots\}$ is called a *Markov renewal sequence* (MRS) with a discrete state space S if for $S_0 = 0, S_{n+1} > S_n$,

$$\begin{aligned} P(X_{n+1} = j, S_{n+1} - S_n \leq x | X_n \\ = i, S_n, X_{n-1}, S_{n-1}, \dots, X_0, S_0) \\ = P(X_{n+1} = j, S_{n+1} - S_n \leq x | X_n = i) \\ = P(X_1 = j, S_1 \leq x | X_0 = i) \end{aligned}$$

for all $n = 0, 1, \dots$

The matrix G is defined by $G(y) = [G_{ij}(y)]$ where

$$G_{ij}(y) = P(X_1 = j, S_1 \leq y | X_0 = i) \text{ for } i, j \in S$$

is called the *kernel of the MRS*. An MRS is well defined by its initial distribution and its kernel.

Let $\{X_n, n = 0, 1, 2, \dots\}$ be a discrete-time stochastic process with a countable state space S . Let Y_n be a sequence of random variables taking values on the nonnegative real line, $S_n = \sum_{k=1}^n Y_k$ and $N(t) = \max\{n : S_n \leq t\}$.

Definition. The continuous-time process $\{X(t), t \geq 0\}$ defined by $X(t) = X_{N(t)}$ is called a *semi-Markov process* (SMP) if the sequence $\{(X_n, Y_{n+1}), n = 0, 1, \dots\}$ satisfies

$$\begin{aligned} P(X_{n+1} = j, Y_{n+1} < y | X_n \\ = i, Y_n, X_{n-1}, Y_{n-1}, \dots, X_1, Y_1, X_0) \\ = P(X_{n+1} = j, Y_{n+1} < y | X_n = i) \\ = G_{ij}(y) \end{aligned}$$

for all $i, j \in S, n = 0, 1, \dots$ and $y \geq 0$.

Definition. A stochastic process $\{Z(t), t \geq 0\}$ with a countable state space S is called a *Markov regenerative process* (MRGP) if there is an (embedded) MRS $\{(X_n, S_n), n = 0, 1, 2, \dots\}$ such that finite-dimensional distributions of the processes

$$\begin{aligned} \{Z(t + S_n), t \geq 0 | X_n = i, Z(u) \text{ for } 0 \leq u < S_n\} \\ \text{and } \{Z(t), t \geq 0 | X_0 = i\} \end{aligned}$$

are identical.

An alternative definition can be given as follows. A stochastic process with a countable state space S is called a *Markov regenerative process* if for all $n = 0, 1, 2, \dots, 0 \leq t_1 \leq t_2 \leq \dots \leq t_n$ and $A_1 \not\subset A_2 \not\subset \dots \not\subset A_n \subset S$,

there exists an S_1 such that $P(S_1 > 0) > 0$, $P(S_1 < \infty) = 1$ and

$$\begin{aligned} P(Z(S_1 + t_1) \in A_1, Z(S_1 + t_2) \in A_2, \dots, \\ Z(S_1 + t_n) \in A_n | Z(S_1), Z(u) \\ \text{for } 0 \leq u < S_1) \\ = P(Z(t_1) \in A_1, Z(t_2) \in A_2, \dots, \\ Z(t_n) \in A_n | Z(0)). \end{aligned}$$

The future probabilities of an MRGP after a transition point S_n depend on the past only through the state at S_n . Continuous-time Markov chains, SMPs, and regenerative processes are special cases of MRGPs.

Example [M/G/1 Queue]. The arrivals to a queue are according to a Poisson process with rate λ and the iid service times have a general distribution with cdf $B(\cdot)$ with mean r . Let $Z(t)$ be the number of customers in the system at time t and let S_n be the n th departure time, $X_n = Z(S_n +)$ be the number of customers left in the system just after the n th departure, Y_n be the n th service time, and $N(t)$ be the number of departures from the queue in t time units. The process defined by $X(t) = X_{N(t)}$ is an SMP with

$$G_{ij}(y) = \begin{cases} \int_0^y \frac{e^{-\lambda x} (\lambda x)^{j-i-1}}{(j-i-1)!} dB(x), & \text{if } i > 0, j \geq i-1 \\ \int_0^y \frac{e^{-\lambda x} (\lambda x)^j}{j!} dB(x), & \text{if } i = 0 \\ 0 & \text{otherwise.} \end{cases}$$

Hence, $Z(t)$ satisfies the definition of MRGP.

Figure 1 demonstrates a sample path of an M/G/1 queue as an MRGP $Z(t)$, the corresponding sample paths of MRS (X_n, S_n) and the SMP $X(t)$. While the SMP $X(t)$ is in state k , the MRGP $Z(t)$ can visit other states such as $j \neq k$.

The next theorem gives a Markov renewal type equation for

$$P_{ij}(t) = P(Z(t) = j | X_0 = i) \text{ for } i, j \in S.$$

Theorem 1. Let $\{Z(t), t \geq 0\}$ be an MRGP with state space S and let $\{(X_n, S_n), n =$

$0, 1, \dots\}$ be the embedded MRS with state space S and kernel G . Then $P_{ij}(t)$ satisfies the Markov renewal type equation

$$\begin{aligned} P_{ij}(t) &= P(Z(t) = j, S_1 > t | X_0 = i) \\ &+ \sum_{k \in S} \int_0^t P_{kj}(t-u) dG_{ik}(u). \end{aligned}$$

LIMITING PROBABILITIES

The transient probabilities are difficult to obtain in most cases. The limiting behavior of an MRGP is given in the following theorem.

Theorem 2. Let $\{Z(t), t \geq 0\}$ be an MRGP with state space $S = \{0, 1, 2, \dots\}$ and let $\{(X_n, S_n), n = 0, 1, \dots\}$ be the embedded MRS with kernel G . Let

$$\begin{aligned} \mu_i &= E(S_1 | X_0 = i), \\ \alpha_{kj} &= E(\text{time spent by } Z(t) \text{ in state } j \text{ for } 0 \leq t < S_1 | X_0 = k). \end{aligned}$$

Suppose that

- (i) the sample paths of $\{Z(t), t \geq 0\}$ are right continuous with left limits,
 - (ii) the SMP $X(t) = X_{N(t)}$ is irreducible, aperiodic and positive recurrent, and
 - (iii) π is a positive solution to $\pi = \pi G(\infty)$.
- Then

$$\lim_{t \rightarrow \infty} P_{ij}(t) = \frac{\sum_{k=0}^{\infty} \pi_k \alpha_{kj}}{\sum_{k=0}^{\infty} \pi_k \mu_k}.$$

The limit result of Theorem 2 can be demonstrated on Fig. 1 as follows:

$$P(Z(t) = j) = \sum_{k=0}^{\infty} P(Z(t) = j, X(S_{N(t)}) = k)$$

$$= \sum_{k=0}^{\infty} P(Z(t) = j | X(S_{N(t)}) = k)$$

$$\times P(X(S_{N(t)}) = k) \text{ and}$$

$$\begin{aligned} \lim_{t \rightarrow \infty} P(Z(t) = j) &= \sum_{k=0}^{\infty} \lim_{t \rightarrow \infty} P(Z(t) \\ &= j | X(S_{N(t)}) = k) \lim_{t \rightarrow \infty} P(X(S_{N(t)}) = k). \end{aligned}$$

Figure 1. Markov regenerative process $Z(t)$, Markov renewal sequence (X_n, S_n) , and semi-Markov process $X(t)$.

The summand of the right side of the equation intuitively is, in the long run, the fraction of the time MRGP is in state j when the embedded SMP is in state k times the fraction of the time the SMP is in state k . From the limiting probabilities of an SMP from Kulkarni [2]

$$\lim_{t \rightarrow \infty} P(X(t) = k) = \frac{\pi_k \mu_k}{\sum_{i=0}^{\infty} \pi_i \mu_i}$$

and

$$\lim_{t \rightarrow \infty} P(Z(t) = j | X(S_{N(t)}) = k) = \frac{\alpha_{kj}}{\mu_k},$$

and the result in Theorem 2 follows.

Example [A Series System]. Consider an equipment with N components. The equipment

works as long as all the components work. Component i works for an *exponential*(λ_i) units of time and its repair takes R_i units of time with cdf $F_i(r)$ and mean r_i . There is a single repairman and components do not fail when one is being repaired. Let $S_0 = 0, S_1, S_2, \dots$ be the successive failure times and X_n be the component causing n th failure. $S_{n+1} - S_n$ consists of a repair and a failure-free time. Then the process $\{(X_n, S_n), n = 0, 1, 2, \dots\}$ is a Markov renewal process with kernel

$$G_{ij}(y) = \int_0^y \lambda_j e^{-u \sum_{i=1}^N \lambda_i} F_i(y - u) du$$

for $i, j = 1, 2, \dots, N$. Then the process $\{Z(t), t \geq 0\}$ defined by

$$Z(t) = \begin{cases} 0, & \text{if the equipment is} \\ & \text{working at time } t \\ i, & \text{if the component } i \text{ is under} \\ & \text{repair at time } t \end{cases}$$

is an MRGP. Note that the MRS or the SMP have the state space $\{1, 2, \dots, N\}$, while the MRGP has the state space $\{0, 1, 2, \dots, N\}$. Then for $i, j = 1, 2, \dots, N$,

$$G_{ij}(\infty) = \frac{\lambda_j}{\sum_{k=1}^N \lambda_k}.$$

For $j = 1, 2, \dots, N$, the limiting probabilities of the embedded MRS are

$$\pi_j = \frac{\lambda_j}{\sum_{k=1}^N \lambda_k},$$

and for $k = 1, 2, \dots, N$, the expected durations are

$$\alpha_{k0} = \frac{1}{\sum_{k=1}^N \lambda_k}$$

$$\alpha_{kk} = r_k$$

$$\alpha_{kj} = 0 \text{ otherwise}$$

$$\mu_k = r_k + \frac{1}{\sum_{j=1}^N \lambda_j}.$$

Then from Theorem 2, the probability that the system is working in the long run is

$$\lim_{t \rightarrow \infty} P_{i0}(t) = \frac{1}{1 + \sum_{k=1}^N r_k \lambda_k}$$

and the probability that the component j is under repair in the long run is

$$\lim_{t \rightarrow \infty} P_{ij}(t) = \frac{r_j \lambda_j}{1 + \sum_{i=1}^N r_k \lambda_k}.$$

MARKOV RENEWAL FUNCTION AND MARKOV RENEWAL-TYPE EQUATIONS

SERHAN ZIYA

Department of Statistics and Operations
Research, University of North Carolina,
Chapel Hill, North Carolina

MARKOV RENEWAL FUNCTION

Suppose that $\{(X_n, T_n), n \geq 0\}$ is a Markov renewal sequence with a corresponding kernel $G(t)$. For $n \geq 0$, X_n takes values from the discrete set E , $\{X(t), t \geq 0\}$ is the semi-Markov process and $\mathbf{N}(t) = \{[N_k(t)]_{k \in E}, t \geq 0\}$ is the Markov renewal process generated by this Markov renewal sequence. For $t \geq 0$, let

$$M_{jk}(t) = \mathbf{E}[N_k(t) | X_0 = j], j, k \in E.$$

Thus, $M_{jk}(t)$ is the expected number of transitions of $\{X(t), t \geq 0\}$ into state k over $(0, t]$ given that the initial state is j . Let $M(t) = [M_{jk}(t)]_{j,k \in E}$ denote the matrix of these expectations. Then, the matrix $M(t)$ is called the *Markov renewal function* generated by the Markov renewal sequence $\{(X_n, T_n), n \geq 0\}$.

Before we move further, we first introduce the matrix convolution notation, which will make the presentation significantly simpler. Suppose that $A(t) = [A_{jk}(t)]$ and $B(t) = [B_{jk}(t)]$ are two matrices of functions so that the product $A(t)B(t)$ is defined. Now, let

$$\begin{aligned} C_{jk}(t) &= \sum_i \int_0^t A_{ji}(t-u) dB_{ik}(u) \\ &= \sum_i \int_0^t dA_{ji}(u) B_{ik}(t-u). \end{aligned}$$

Then, the matrix $C(t) = [C_{ij}(t)]$ is called the *convolution* of A and B (and written as $C(t) = A * B(t)$).

In the analysis of Markov renewal processes, one frequently uses “Markov renewal arguments,” which is the idea of first obtaining an expression for whatever is of interest

by conditioning on the first sojourn time T_1 and the first state the Markov renewal sequence visits, X_1 . We next use the Markov renewal argument to determine an expression for the Markov renewal equation.

By conditioning on X_1 and T_1 , we obtain

$$\begin{aligned} \mathbf{E}[N_k(t) | X_0 = j, X_1 = i, T_1 = s] \\ = \begin{cases} \delta_{ik} + M_{ik}(t-s), & s \leq t, \\ 0, & s > t, \end{cases} \end{aligned}$$

where $\delta_{ik} = 1$ if $i = k$ and zero otherwise.

Using this equation, one can show that

$$M_{jk}(t) = \int_0^t dG_{jk}(s) + \sum_{i \in E} \int_0^t M_{ik}(t-s) dG_{ji}(s),$$

which, in matrix form, can also be written as

$$M(t) = G(t) + G * M(t). \quad (1)$$

Equation (1) is called the *Markov renewal equation*.

Now, suppose that $H_j(\cdot)$ is the sojourn time distribution for state j for the Markov renewal sequence $\{(X_n, T_n), n \geq 0\}$ and suppose that there exists positive ε and α such that $H_i(\alpha) < 1 - \varepsilon$ for $i \in E$. This condition essentially ensures the regularity of the process by preventing sojourn times to be consistently too small so that up to any point in time t , the total number of renewals is always finite. To be more precise, as Kulkarni [1] shows, under this condition, the process $\{N(t), t \geq 0\}$ where $N(t) = \max\{n \geq 0 : T_n \leq t\}$ is regular, that is, $N(t) < \infty$ for all $0 \leq t < \infty$ with probability 1.

Under the same regularity condition, by repeatedly using the Markov renewal equation (1), one can show that

$$M(t) = \sum_{i=1}^{\infty} G^{*i}(t) \text{ for } t \geq 0,$$

where $G^{*i}(\cdot)$ is the i -fold convolution of the matrix $G(\cdot)$ with itself.

MARKOV RENEWAL-TYPE EQUATIONS AND THEIR SOLUTION

In the previous section, we used a Markov renewal argument to derive an expression for the Markov renewal function and obtained the Markov renewal equation (1). In general, when we use the Markov renewal argument, we usually end up with the following generalized version of Equation (1), which we call Markov renewal-type equation

$$R(t) = D(t) + G * R(t).$$

In this equation, typically, $D(t)$ and $G(t)$ are known and the objective is to determine $R(t)$. Under certain conditions on $D(t)$ and the regularity condition on $G(t)$, which we described in the previous section, it is known that there exists a unique solution given by

$$R(t) = D(t) + M * D(t), \quad (2)$$

where $M(t)$ is the Markov renewal function associated with kernel $G(\cdot)$. (For a formal statement of this result, see Kulkarni [1]).

Even though Equation (2) gives the solution for $R(\cdot)$, it is usually not used for computational purposes. It is, however, crucial in establishing the key Markov-renewal theorem, which gives the expression for the limiting behavior of $R(t)$, and is one of the most fundamental results in Markov renewal theory.

OTHER SOURCES

For more on Markov renewal functions and Markov renewal-type equations, we refer the reader to Cinlar [2] and Kulkarni [1], from which the author of this article has also benefited.

MARKOV RENEWAL PROCESSES

SERHAN ZIYA

Department of Statistics and
Operations Research,
University of North Carolina,
Chapel Hill, North Carolina

Markov renewal processes are a generalization of renewal processes. While a renewal process is a counting process that keeps track of the number of occurrences of a certain type of event associated with a stochastic process, a Markov renewal process is a vector-valued process that keeps a separate count of these events depending on the state of the stochastic process at the times these events occur. For example, while a renewal process would simply keep track of the number of arrivals at a queueing system, a Markov renewal process could help keep a separate count of the arrivals depending on the queue lengths they observe.

MARKOV RENEWAL SEQUENCES

In order to clearly define Markov renewal processes, it helps to introduce Markov renewal sequences first. Consider a sequence of bivariate random variables $\{(X_n, T_n), n \geq 0\}$ where $T_0 = 0$, $T_n \leq T_{n+1}$, and X_n takes values in a discrete set E for all $n \geq 0$. Suppose that the following condition holds for all $n \geq 0$:

$$\begin{aligned} P\{X_{n+1} = j, T_{n+1} - T_n \leq t | X_n = i, T_n, X_{n-1}, \\ T_{n-1}, \dots, X_0, T_0\} \\ = P\{X_{n+1} = j, T_{n+1} - T_n \leq t | X_n = i\} \\ = P\{X_1 = j, T_1 \leq t | X_0 = i\}. \end{aligned} \quad (1)$$

Then, the stochastic process $\{(X_n, T_n), n \geq 0\}$ is said to be a Markov renewal sequence. Thus, a Markov renewal sequence satisfies the Markov property at each $n \geq 0$ since by Condition (1), the future stochastic evolution of the process depends on the past only through the system state X_n at n .

Markov renewal sequences form the basic structure of some of the important classes of stochastic processes such as semi-Markov processes and Markov regenerative processes. A continuous-time stochastic process with a countable state space and piecewise constant, right-continuous sample paths is called a *semi-Markov process* if the process $\{(X_n, T_n), n \geq 0\}$ where T_n is the time of the n th jump epoch for the process and X_n is the system state right after T_n is a Markov renewal sequence. In other words, for a continuous-time stochastic process to be a semi-Markov process, a Markov renewal sequence must arise at times where the process makes jumps. If there exists a Markov renewal sequence embedded in a continuous-time stochastic process (not necessarily at jump points but perhaps at some other carefully chosen instances), the stochastic process is said to be a Markov regenerative process.

We next discuss how to describe a Markov renewal sequence. Suppose that $\alpha_i = P\{X_0 = i\}$ is the probability that the initial state is i and $G_{ij}(t) = P\{X_1 = j, T_1 \leq t | X_0 = i\}$. Then, it can be easily shown that the Markov renewal sequence is completely characterized by the initial distribution $\alpha = [\alpha_i]_{i \in E}$ and the matrix $G(y) = [G_{ij}(y)]_{i,j \in E}$, which is called the *kernel of the Markov renewal sequence*.

Since the sequence $\{(X_n, T_n), n \geq 0\}$ satisfies the Markov property at all $n \geq 0$, it is also easy to see that the process $\{X_n, n \geq 0\}$ is a discrete-time Markov chain with the same initial distribution as the Markov renewal sequence and transition probability matrix P defined by $P = G(\infty)$ with the exception that $P_{ii} = 1$ whenever $\sum_{j \in E} G_{ij}(\infty) = 0$ for some $i \in E$. On the other hand, any discrete-time Markov chain can be seen as a Markov renewal sequence where $T_n = n$ for all $n \geq 0$.

MARKOV RENEWAL PROCESSES

Suppose that $\{(X_n, T_n), n \geq 0\}$ is a Markov renewal sequence as defined in the section titled "Markov Renewal Sequences" and let $\{N(t), t \geq 0\}$ be a counting process defined as

$$N(t) = \sup \{n \geq 0 : T_n \leq t\}.$$

We say that the process $\{N(t), t \geq 0\}$ is regular if $N(t) < \infty$ with probability 1 for all $0 \leq t < \infty$. Now, for $i \in E$, define

$$F_i(t) = P\{T_1 \leq t \mid X_0 = i\} = \sum_{j \in E} G_{ij}(t).$$

Then, Kulkarni [1] shows that one sufficient condition for $\{N(t), t \geq 0\}$ to be regular is that there exists positive ε and δ such that $F_i(\delta) < 1 - \varepsilon$ for all $i \in E$. Note that this condition essentially prevents T_n 's take very small values with probability 1.

Assuming that $\{N(t), t \geq 0\}$ is regular, we define a new process

$$X(t) = X_{N(t)} \text{ for } t \geq 0.$$

Then, $\{X(t), t \geq 0\}$ is a semi-Markov process and it is said to be the semi-Markov process generated by the Markov renewal sequence $\{(X_n, T_n), n \geq 0\}$.

Now, define $N_k(t)$ to be the number of times the semi-Markov process visits state k over the interval $(0, t]$. Then, the stochastic vector process $\mathbf{N}(t) = \{[N_k(t)]_{k \in E}, t \geq 0\}$ is said to be the Markov renewal process generated by the Markov renewal sequence $\{(X_n, T_n), n \geq 0\}$.

Remark. The reader should note that the use of the terms Markov renewal sequence and Markov renewal process is not consistent in the literature. The definitions of these terms given in this article follow those in Kulkarni [1]. The definition of Markov renewal process given in Heyman and Sobel [2] is the same as that in Kulkarni [1], however, Cinlar [3] and Kihlbas [4] use the term Markov renewal process to refer to the process defined as Markov renewal sequence in this article and in Kulkarni [1].

EXAMPLES

In this section, we provide a number of examples where Markov renewal sequences and Markov renewal processes appear.

Example 1. Suppose that $\{X(t), t \geq 0\}$ is a continuous-time Markov chain. Let T_n denote the n th time the Markov chain makes a jump and define X_n to be the system state right after the n th jump, that is, $X_n = X(T_n+)$. Then, since in a continuous-time Markov chain, Markov property holds at all times, it also holds at jump epochs, and thus we conclude that $\{(X_n, T_n), n \geq 0\}$ is a Markov renewal sequence. Clearly, the continuous-time Markov chain $\{X(t), t \geq 0\}$ is also the semi-Markov process generated by the Markov renewal sequence $\{(X_n, T_n), n \geq 0\}$. Therefore, if we define $N_k(t)$ to be the number of times the Markov chain visits state k over $(0, t]$, we can see that the vector stochastic process $\mathbf{N}(t) = \{[N_k(t)]_{k \in E}, t \geq 0\}$ is a Markov renewal process.

Example 2. Suppose that $\{Q(t), t \geq 0\}$ is the queue length process for the G/M/1 queue. Let $H(\cdot)$ denote the cumulative distribution function for the interarrival times and μ denote the exponential service rate.

Define T_n to be the arrival time of the n th customer and $X_n = Q(T_n-)$. Thus, X_n is the queue length the n th arriving customer sees. Now, since service times are exponentially distributed, at arrival points the queue length process has the Markov property, that is, its future evolution depends on the past only through the queue lengths at those times. Thus, $\{(X_n, T_n), n \geq 0\}$ is a Markov renewal sequence and its kernel can be expressed as

$$G_{ij}(t) = \begin{cases} \int_0^t \frac{e^{-\mu s} (\mu s)^{i+1-j}}{(i+1-j)!} dH(s), & 1 \leq j \leq i+1, \\ H(t) - \sum_{k=1}^{i+1} G_{ik}(t), & j = 0. \end{cases}$$

Let $N_k(t)$ denote the number of arrivals over $(0, t]$ who find k customers at the time of their arrival. One can see that $N_k(t)$ is also the number of times the semi-Markov process generated by the Markov renewal sequence $\{(X_n, T_n), n \geq 0\}$ visits state k over $(0, t]$. Thus, $\mathbf{N}(t) = \{[N_k(t)]_{k \in E}, t \geq 0\}$ is a Markov renewal process.

Example 3. Suppose that a new machine has a random lifetime with a cumulative distribution function $A(\cdot)$. Once the machine fails, it is repaired, and the repaired machine becomes as good as new. The repair time depends on the amount of time the machine has been operational since the last repair. If the machine remains operational less than T units of time before it fails, then the repair time distribution is given by $B_1(\cdot)$. Otherwise, the distribution is given by $B_2(\cdot)$. Let $X(t)$ denote the state of the machine at time t . If $X(t) = 0$, that means the machine is operational at time t . If $X(t) = i$ where $i \in \{1, 2\}$, that means the machine is going through a repair of type i at time t . Let X_n denote the state of the machine after the n th jump of the process $\{X(t), t \geq 0\}$ and T_n denote the time of the n th jump. Then $\{(X_n, T_n), n \geq 0\}$ is a Markov renewal sequence with the following kernel.

$$G(t) = \begin{bmatrix} 0 & A(t) & 0 \\ B_1(t) & 0 & 0 \\ B_2(t) & 0 & 0 \end{bmatrix} \text{ if } t \leq T$$

and

$$G(t) = \begin{bmatrix} 0 & A(T) & A(t) - A(T) \\ B_1(t) & 0 & 0 \\ B_2(t) & 0 & 0 \end{bmatrix} \text{ if } t > T.$$

Note also that $\{X(t), t \geq 0\}$ is a semi-Markov process and, in fact, the semi-Markov process generated by the Markov renewal sequence $\{(X_n, T_n), n \geq 0\}$.

Now, let $N_0(t)$ denote the number of times the machine is repaired and $N_i(t)$ denote the number of times the machine has started a type i repair over the time interval $(0, t]$. Then, $N_k(t)$ is the number of times the semi-Markov process $\{X(t), t \geq 0\}$ visited state k over $(0, t]$ and thus $\mathbf{N}(t) = \{[N_k(t)]_{k \in E}, t \geq 0\}$ is a Markov renewal process.

OTHER SOURCES

For more on Markov renewal processes, we refer the reader to Cinlar [3], Heyman and Sobel [2], Kohlas [4], and Kulkarni [1], from which the author of this article has also benefited. Cinlar [3] and Kulkarni [1], in particular, provide a comprehensive coverage of Markov renewal process including key results that are typically used in the analysis of these processes.

INTRODUCTION

Every one has seen a point process in action in one form or the other in day-to-day activities. For example, on a regular basis we all visit a grocery store or a post office or a bank or a restaurant or a drive-through place such as a fast food restaurant or a coffee place. Each customer can be thought of as a “point” arriving to the “place of interest” with some “work” to be done. These points arrive at random times (in some cases in batches) and the associated amounts of work can be characterized by another set of random variables. Mathematically, a point process $\{X_n\}$ is a sequence of random variables that may represent epochs at which certain events occur. Associated with these epochs are other random variables, $\{Y_n\}$ that contain further information about the events. Each pair (X_n, Y_n) is said to be a *marked point*, and the sequence $\{(X_n, Y_n)\}$ is called a *marked point process* (MPP). For example, in a drive-through coffee house, the quantity X_n will represent the time of the n th car (since the last car) to the place where the order is given, and Y_n may stand for the amount (in dollars) of the n th order or the time the n th order is picked up (at the next window) from the time it was placed. It is possible that $\{Y_n\}$ could be a vector process. So, going back to the earlier example, the first component of Y_n can be taken as the amount of the order and the second component is the time to pick up the order.

Why do we need to study a point process? Modeling plays an important role in practice. Models are representations of objects, processes, or anything that we wish

to describe or whose patterns of behavior we wish to analyze. They enable us to understand the behavior of complex systems. Modeling is an iterative process involving several stages. They can be summarized as follows:

- *Formulation Stage.* Study the problem; propose a model.
- *Solution Stage.* Choose appropriate tools to bring out essential characteristics of the model.
- *Validation Stage.* Verify the model and propose modification, if any.

There are basically two types of modeling: deterministic modeling and stochastic modeling. The *deterministic models* include topics such as mathematical programming (linear and nonlinear programming), scheduling, and sequencing. The *stochastic modeling* (also referred to as *probabilistic modeling*) covers areas such as Markov processes, queueing theory, reliability theory, warranty analysis, inventory, and probabilistic scheduling. Note that *statistical modeling* that deals with the study of uncertainty and variability is subsumed in stochastic modeling.

Going back to our drive-through coffee house example, a prudent management would be interested to see how the arrivals occur (including the pattern of arrivals) so as to schedule its workforce as well as to upgrade its service facility for continuous improvement. The formulation stage of the modeling involves a good understanding of the point process describing the underlying arrivals.

MAP IN CONTINUOUS TIME

Point processes can be studied in discrete time or in continuous time, depending on the nature of applications in which these processes are used. First, we will discuss Markovian arrival process (MAP) in continuous time by highlighting the building blocks for this process.

Poisson Process

One of the most celebrated point processes in continuous time is the classical Poisson process (see **Poisson Process and its Generalizations**). Since this process is a building block for the MAP, we will briefly revisit the Poisson process. Suppose that the interarrival times of the cars to the drive-through coffee house are independent and identically distributed with the common probability density function, $f(t)$, and the cumulative distribution function, $F(t)$, given by

$$f(t) = \lambda e^{-\lambda t}, t \geq 0, F(t) = 1 - e^{-\lambda t}, t \geq 0, \quad (1)$$

where $\lambda > 0$ and gives the average rate of cars arriving per unit of time.

The counting process $\{N(t), t \geq 0\}$ giving the number of cars arriving at the place of order in the drive-through coffee house during $(0, t]$ plays an important role, notably, in stochastic models. Denoting by $p_n(t) = P(N(t) = n)$ it can easily be verified that the following differential-difference equations are satisfied (see **Poisson Process and its Generalizations**):

$$\begin{aligned} p'_0(t) &= -\lambda p_0(t), \\ p'_n(t) &= -\lambda p_n(t) + \lambda p_{n-1}(t), \quad n = 1, 2, 3, \dots \end{aligned} \quad (2)$$

subject to the initial conditions

$$p_0(0) = 1 \text{ and } p_n(0) = 0, n = 1, 2, 3, \dots \quad (3)$$

Equations (2) and (3) can be solved to give an explicit solution for $p_n(t)$ as

$$p_n(t) = \frac{(\lambda t)^n}{n!} e^{-\lambda t}, n = 0, 1, 2, \dots \quad (4)$$

The renewal function, $H(t) = E[N(t)]$, and its density are given by

$$H(t) = \lambda t \text{ and } h(t) = H'(t) = \lambda. \quad (5)$$

Why Phase-Type Distributions?

In practice, the qualitative aspects of stochastic models are studied mostly through

well-planned computation. Computing is both an art and science. It has become an integral and important part of the analysis of any stochastic model. Those days are gone when one had the need to have *explicit* analytical solutions. Algorithmic or computational probability plays a major role in the analysis and implementation of stochastic models in practice. Computational aspects are not a luxury any more! Modern day development of algorithmic probability is mainly due to Neuts [1].

Poisson processes and exponential distributions have very nice mathematical properties that make queueing models with these as arrival processes or service-time distributions very attractive and tractable. However, these assumptions are highly restrictive in application. Thus, seeing this limitation, Neuts [1] first developed the theory of phase-type (PH) distributions (see **Phase-Type (PH) Distributions**) and related point processes. In stochastic modeling, PH distributions lend themselves naturally to algorithmic implementation. They have nice closure properties and a related matrix formalism that make them attractive for use in practice (see **Phase-Type (PH) Distributions**).

PH distributions are natural generalizations of exponential distributions and have found tremendous applications among others in queueing, reliability, inventory, and warranty models. Furthermore, these distributions require simple matrix formalism not only in the analysis but also in algorithmic implementation. PH distributions can easily be incorporated into undergraduate curriculum as students are exposed to matrix theory and basic probability in almost all engineering curricula.

Like Poisson process, PH-renewal process forms the (second) building block in the development of MAP. For the sake of continuity, we will only highlight key aspects of PH distributions and refer the reader to article titled **Phase-Type (PH) Distributions** of this handbook for complete details.

Continuous Phase-Type Distributions. Suppose that $\{Y_t\}$ is continuous-time Markov chain (CTMC) on $\{1, 2, \dots, m, m+1\}$ with m transient states $1, 2, \dots, m$ and an absorbing state $m+1$. For details on CTMC, we refer

the reader to the section titled “Continuous-Time Markov Chains (CTMCs)” of this handbook. The generator of the Markov chain (MC) is of the form

$$\tilde{Q} = \begin{bmatrix} S & \mathbf{S}^0 \\ \mathbf{0} & 0 \end{bmatrix}, \quad (6)$$

where S is an $m \times m$ matrix, $\mathbf{S}^0$ is a column vector of order m such that $\mathbf{S}\mathbf{e} + \mathbf{S}^0 = \mathbf{0}$. Assume that the matrix $\mathbf{S}\mathbf{e} + \mathbf{S}^0$ is irreducible. Let $(\beta_1, \dots, \beta_m, \beta_{m+1}) = (\beta, \beta_{m+1})$ be a probability vector giving the initial probabilities. That is, $P(Y_0 = i) = \beta_i, 1 \leq i \leq m+1$. Suppose we start the CTMC in one of the m transient states. We are interested in finding the time until absorption into the absorbing state.

Let X denote the time *until* absorption into state $m+1$. Then X is a continuous random variable on $[0, \infty)$ and its probability density and cumulative probability distribution functions are given by (we assume that $\beta_{m+1} = 0$ which is the case in most applications)

$$\begin{aligned} f(t) &= \beta e^{\mathbf{S}t} \mathbf{S}^0, \quad t \geq 0, \\ F(t) &= P(X \leq t) = 1 - \beta e^{\mathbf{S}t} \mathbf{e}, \quad t \geq 0. \end{aligned} \quad (7)$$

In this case, we say that X follows a PH distribution with representation (β, S) of order m and denote this by $X \sim \text{PH}(\beta, S)$ of order m . The mean and variance of X are given by

$$\mu_X = \beta(-S)^{-1} \mathbf{e} \text{ and } \sigma_X^2 = 2\beta S^{-2} \mathbf{e} - \mu_X^2. \quad (8)$$

In Equation (7) and also in the sequel, we will be using the exponential matrix frequently. Exponential matrix is defined as $e^A = \sum_{n=0}^{\infty} \frac{A^n}{n!} = I + A + \frac{A^2}{2!} + \dots$. Some well-known distributions such as exponential, (generalized) Erlang, and hyperexponential are special cases of PH distributions (see **Phase-Type (PH) Distributions**). There are some interesting closure properties associated with the PH distributions and can be seen in Ref. 1 (also see **Phase-Type (PH) Distributions**).

Going back to our drive-through coffee house example, suppose that the interarrival times of successive cars to the drive-through coffee house are independent and identically

distributed with the common probability density function $f(t)$ as given in Equation (7). That is, we are assuming the interarrival times to be of the phase type with representation (β, S) of order m . The underlying CTMC is governed by the generator given in Equation (6). Let $\{N(t), t \geq 0\}$ denote the associated counting process, giving the number of cars arriving at the place of order in the drive-through coffee house during $(0, t]$.

Denoting by $P(n, t) = \{P_{ij}(n, t)\}$, for $n \geq 0, t \geq 0$, the (i, j) th element of $m \times m$ matrices is defined as

$$P_{ij}(n, t) = P(N(t) = n, Y_t = j | N(0) = 0, Y_0 = i), \quad (9)$$

for $n \geq 0, t \geq 0, 1 \leq i, j \leq m$. These matrices satisfy the following differential equations (Ref. 1 and see **Phase-Type (PH) Distributions**) where we assume that $\beta_{m+1} = 0$ which is the case in most applications. That is, $F(0) = 0$.

$$\begin{aligned} P'(0, t) &= SP(0, t) = P(0, t)S, \\ P'(n, t) &= SP(n, t) + \mathbf{S}^0 \beta P(n-1, t) \\ &= P(n, t)S + P(n-1, t) \mathbf{S}^0 \beta, \end{aligned} \quad (10)$$

with the initial conditions $P(n, 0) = 0$ for $n \geq 1$, and $P(0, 0) = I$, an identity matrix of order m .

The computation of the matrices $\{P(n, t): \text{for } n \geq 0, t \geq 0\}$ can be carried out efficiently and will be shown in a more general context when dealing with MAP.

Note that the PH-renewal process is related to the irreducible MC obtained by instantaneously restarting the absorbing MC (whose generator is as given in Eq. 6) with the same initial probability vector β every time an absorption occurs. Thus, the PH-renewal process is related to the irreducible MC with generator

$$Q^* = S + \mathbf{S}^0 \beta. \quad (11)$$

The stationary probability vector, π^* of Q^* satisfying $\pi^* Q^* = \mathbf{0}, \pi^* \mathbf{e} = 1$, is given by

$$\pi^* = \frac{1}{\mu_X} \beta(-S)^{-1}, \quad (12)$$

where μ_X is the mean of X and is given in Equation (8).

The renewal function, $H(t) = E[N(t)]$, and its density for the PH-renewal process are given by the following equation (Ref. 1 and also see **Phase-Type (PH) Distributions**):

$$H(t) = \frac{1}{\mu_X} \left\{ t + \frac{\sigma_X^2 + \mu_X^2}{2\mu_X} + \beta [e\pi^* - e^{Q^*t}] S^{-1} \mathbf{e} \right\}$$

and

$$h(t) = H'(t) = \beta e^{Q^*t} \mathbf{S}^0. \quad (13)$$

Why Markovian Arrival Process?

In practice, we come across many situations where the arrival processes are not necessarily renewal processes. For example, consider a queueing network consisting of, say, 2 nodes. The output of node 1 will form the input to node 2. If we consider non-Poisson arrivals, say, to the first node, the output process will not necessarily be a renewal process. Also, in production line problems where arrivals from different sources form input to an assembly system, the arrival process may not necessarily be a renewal process. So, how do we model these point processes? The answer is to use MAP.

History of MAP. Earlier, we talked about how important it is to have algorithmic aspects built into the analysis and implementation of any stochastic model in practice. During the 1970s, with a genuine concern for the usefulness of stochastic models in practice, Neuts developed algorithmic probability and matrix-analytic methods (see **Matrix Analytic Method: Overview and History**): In the first stage of that development, he introduced PH distributions. In the second stage, Neuts developed matrix geometric methods in queueing and popularized the algorithmic methods as a way to study stochastic models. Then he introduced MAP, a versatile point process that not only generalized the PH-renewal process but also provided a way to model correlated arrivals that had largely been ignored in the literature.

What is a Markovian Arrival Process?

Consider an irreducible CTMC with m transient states. At the end of a sojourn in state i , that is exponentially distributed with parameter λ_i , there are two possibilities. The first possibility corresponds to an “event” (or an arrival) and the CTMC can visit any of the m transient states including the state from which this event occurred with probability p_{ij} . The second possibility corresponds to no arrival and the CTMC can visit any of the $m - 1$ transient states (all m except i) with probability q_{ij} . Thus, the CTMC can go from state i to state i only through an arrival. Define matrices $D_0 = (d_{ij}^{(0)})$ and $D_1 = (d_{ij}^{(1)})$ such that $d_{ii}^{(0)} = -\lambda_i$, $1 \leq i \leq m$; $d_{ij}^{(0)} = \lambda_i q_{ij}$, $j \neq i$, $1 \leq i, j \leq m$; $d_{ij}^{(1)} = \lambda_i p_{ij}$, $1 \leq i, j \leq m$, with $\sum_j p_{ij} + \sum_{j \neq i} q_{ij} = 1$, for $1 \leq i \leq m$. By assuming D_0 to be a nonsingular matrix, the successive times between “events” (or arrivals) will be finite with probability one and the process will not terminate. A pictorial description of this process is given in Fig. 1.

Thus, a MAP is described by the two parameter matrices (D_0, D_1) of order m such that the transitions corresponding to no arrivals are governed by D_0 and the transitions corresponding to arrivals are governed by D_1 . The underlying CTMC has the generator given by $Q = D_0 + D_1$. This representation of MAP is a special case of batch Markovian arrival process (BMAP) (see **Batch Markovian Arrival Processes (BMAP)**) with batch size equal to 1. This

Figure 1. Description of MAP.

BMAP was originally introduced by Neuts [2] as a *versatile Markovian point process* (VMPP) in 1979. The original description of the VMPP was quite involved with heavy notation due to several different types of arrivals that are to be accounted explicitly. Lucantoni, Meier-Hellstern, and Neuts [3] introduced the terms MAP and BMAP to describe the VMPP with much simpler notation. It has now become a standard notation in describing MAP and BMAP. The reason for using the term BMAP rather than the originally coined term VMPP is that, at the time, it was thought that the VMPP is a special class of BMAP. Later, it was realized that the VMPP and BMAP are equivalent processes [4].

The point process described by the MAP is a special class of semi-Markov processes with transition probability matrix given by

$$\int_0^t e^{D_0 x} D_1 dx = [I - e^{D_0 t}](-D_0)^{-1} D_1. \quad (14)$$

Let π be the steady state probability vector of the generator Q governing the underlying CTMC satisfying

$$\pi Q = \mathbf{0}, \pi \mathbf{e} = 1. \quad (15)$$

Let α be the initial probability vector of the underlying CTMC with generator Q . We can choose α in a variety of ways to model different scenarios. For example, if we want the time origin to coincide with an arbitrary arrival point, we can take $\alpha = c\pi D_1$, where c is the normalizing constant to make the vector α a probability vector. Other scenarios include the time origin to be the end of an interval during which there are at least k arrivals, the point at which the system is in specific state such as when the busy period ends or busy period begins. The most interesting case is the one where we get the stationary version of the MAP by $\alpha = \pi$.

The fundamental rate (the rate of arrivals per unit of time), λ , is given by

$$\lambda = \pi D_1 \mathbf{e}. \quad (16)$$

Often, in model comparisons it is convenient to select the timescale of the MAP so

that λ has a certain value. This is accomplished by multiplying the parameter matrices D_0 and D_1 by the appropriate common constant.

The stationary MAPs are dense in the family of all stationary MPPs [5]. Thus, MAPs can be used to represent a wide range of applications in point processes.

Special Cases of MAP. A number of well-known and useful processes are obtained as special cases of MAP. Some examples are given below:

1. *Poisson Process.* Suppose that the interarrival times are exponentially distributed with parameter η . Then in this case, we have $m = 1$, $D_0 = -\eta, D_1 = \eta$.
2. *PH-Renewal Process.* Suppose that the interarrival times are of PH with representation (β, S) of order m . Then this is a particular case of MAP with $D_0 = S, D_1 = S^0 \beta$.
3. *Markov-Modulated Poisson Process.* This is a doubly stochastic Poisson process in which the instantaneous arrival rate depends on an auxiliary Markov process. Suppose that the Markov process has the generator Q of order m . When that Markov process is in state i , arrivals occur at rate λ_i . Then, the MMPP with (single) arrivals is a MAP with $D_0 = Q - \Delta(\lambda), D_1 = \Delta(\lambda)$, where $\Delta(\lambda)$, is a diagonal matrix whose i th diagonal entry is given by λ_i . Thus, in this MAP arrival, transitions do not change the current state of the underlying CTMC. Note that a two-state MMPP in which only one diagonal of $\Delta(\lambda)$ is positive is the *interrupted Poisson process* (IPP).
4. *Markov-Switched Poisson Process.* Suppose we consider a point process that consists of geometric runs of intervals that are exponentially distributed with rates depending on the state of the underlying discrete-time Markov chain (DTMC) with m transient states and with transition probability matrix P . This process is a MAP with $D_0 = -\Delta(\lambda)$

and $D_1 = \Delta(\lambda)P$, where $\Delta(\lambda)$ is a diagonal matrix whose i th diagonal entry is given by λ_i . In this special case of MAP, only arrivals can change the current state of the underlying CTMC.

5. *PH Semi-Markov Process.* Consider a semi-Markov process $\{(X_n, Y_n) : n \geq 0\}$

with PH interval distributions; the conditional distribution of X_n given $Y_n = i$ is a PH distribution with representation $(\beta(i), S(i))$ of order m_i and $P(Y_{n+1} = j | Y_n = i) = p_{ij}$, $1 \leq i, j \leq r$. This is a MAP with parameter matrices D_0 and D_1 that are given by

$$D_0 = \begin{bmatrix} S(1) & 0 & \cdots & 0 \\ 0 & S(2) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & S(r) \end{bmatrix}, D_1 = \begin{bmatrix} p_{11}\mathbf{S}^0(1)\beta(1) & p_{12}\mathbf{S}^0(1)\beta(2) & \cdots & p_{1r}\mathbf{S}^0(1)\beta(r) \\ p_{21}\mathbf{S}^0(2)\beta(1) & p_{22}\mathbf{S}^0(2)\beta(2) & \cdots & p_{2r}\mathbf{S}^0(2)\beta(r) \\ \vdots & \vdots & \ddots & \vdots \\ p_{r1}\mathbf{S}^0(r)\beta(1) & p_{r2}\mathbf{S}^0(r)\beta(2) & \cdots & p_{rr}\mathbf{S}^0(r)\beta(r) \end{bmatrix}.$$

The Probability Functions of MAP. Suppose that Z denotes the time to the first arrival in a MAP with representation (D_0, D_1) of order m . The cumulative probability distribution function (CDF) and the probability density function of Z are given by

$$F(t) = \alpha[I - e^{D_0 t}](-D_0)^{-1}D_1\mathbf{e}, \text{ for } t \geq 0, \\ f(t) = \alpha e^{D_0 t}D_1\mathbf{e}, \text{ for } t \geq 0. \quad (17)$$

By taking $\alpha = \pi$, we get the stationary version for $F(\cdot)$. By taking $\alpha = (\pi D_1 \mathbf{e})^{-1} \pi D_1$, $F(\cdot)$ is the CDF of two successive arrivals in the stationary version.

Measures of MAP. Let μ_Z and σ_Z^2 denote respectively the mean and variance of Z . Then we have

$$\mu_Z = \frac{\pi D_1 (-D_0)^{-1} \mathbf{e}}{\pi D_1 \mathbf{e}} = \frac{1}{\pi D_1 \mathbf{e}} = \frac{1}{\lambda} \text{ and} \\ \sigma_Z^2 = \frac{2}{\lambda} \pi (-D_0)^{-1} \mathbf{e} - \frac{1}{\lambda^2}. \quad (18)$$

The Laplace–Stieltjes transform (LST) of the joint distribution of the first n intervals between arrivals is given by

$$\Phi(s_1, \dots, s_n) \\ = \alpha (s_1 I - D_0)^{-1} D_1 \dots (s_n I - D_0)^{-1} D_1 \mathbf{e}. \quad (19)$$

By taking $\alpha = (\pi D_1 \mathbf{e})^{-1} \pi D_1$, the serial correlation, $\rho(Z_1, Z_n)$, of the first, Z_1 , and the

n th, Z_n , interarrival times, is given by

$$\rho(Z_1, Z_n) \\ = \frac{\frac{1}{\lambda} \pi [(-D_0)^{-1} D_1]^{n-1} (-D_0)^{-1} \mathbf{e} - \frac{1}{\lambda^2}}{\frac{2}{\lambda} \pi (-D_0)^{-1} \mathbf{e} - \frac{1}{\lambda^2}}. \quad (20)$$

Generally speaking, in most applications one is interested in correlation between successive intervals. That is, we are interested in $\rho(Z_1, Z_2)$, of Z_1 and Z_2 .

Counting Process of MAP. Let $\{N(t), t \geq 0\}$ denote the associated counting process in the MAP with representation (D_0, D_1) of order m . Suppose that $\{Y_t\}$ denotes the state of the underlying CTMC with generator $Q = D_0 + D_1$. Denoting by $P(n, t) = \{P_{ij}(n, t)\}$, for $n \geq 0, t \geq 0$, the $m \times m$ matrices' (i, j) th element is defined as

$$P_{ij}(n, t) = P(N(t) = n, Y_t = j | N(0) = 0, Y_0 = i), \quad (21)$$

for $n \geq 0, t \geq 0, 1 \leq i, j \leq m$. These matrices satisfy the following differential equations [6]:

$$P'(0, t) = P(0, t)D_0, \\ P'(n, t) = P(n, t)D_0 + P(n-1, t)D_1, \quad (22)$$

with the initial conditions $P(n, 0) = 0$ for $n \geq 1$, and $P(0, 0) = I$, an identity matrix of order m .

The MAP can be viewed as a two-dimensional Markov process $\{(N(t), Y_t)\}$ on

the state space $\{(i, j) : i \geq 0, 1 \leq j \leq m\}$ with the infinitesimal generator given by

$$\hat{Q} = \begin{bmatrix} D_0 & D_1 & & & \\ & D_0 & D_1 & & \\ & & D_0 & D_1 & \\ & & & D_0 & \ddots \\ & & & & D_0 & \ddots \end{bmatrix}. \quad (23)$$

The exponential of the matrix in Equation (23) plays an important role and is given by

$$e^{\hat{Q}t} = \begin{bmatrix} P(0,t) & P(1,t) & P(2,t) & P(3,t) & \cdots \\ & P(0,t) & P(1,t) & P(2,t) & \cdots \\ & & P(0,t) & P(1,t) & \cdots \\ & & & P(0,t) & \cdots \\ & & & & \ddots \end{bmatrix}. \quad (24)$$

An efficient algorithm based on the *uniformization method* for computing the matrices in Equation (24) is discussed in Ref. 7. Jensen [8] first described the uniformization method, also called the method of randomization. It is a powerful method in the sense that (i) it allows us to interpret a continuous-time Markov process as a DTMC in which the constant times between any two transitions are replaced by independent exponential variables with the same parameter; (ii) it avoids the use of differential equations to evaluate the transition matrix.

Computation of $P(n, t)$. Defining

$$\theta \geq \max_i \{(-D_0)_{ii}\}, K = I + \frac{1}{\theta} \hat{Q},$$

$$C_0 = I + \frac{1}{\theta} D_0, \text{ and } C_1 = \frac{1}{\theta} D_1, \quad (25)$$

the uniformization method allows the computation of $e^{\hat{Q}t}$ in terms of a partial sum of the series [7]:

$$e^{\hat{Q}t} = e^{-\theta t} e^{K\theta t} = \sum_{r=0}^{\infty} e^{-\theta t} \frac{(\theta t)^r}{r!} K^r. \quad (26)$$

Since $\hat{Q} = \theta(K - I)$ (Eq. 25), using the form of $\hat{Q}$ as given in Equation (23), we see that

$$K = \begin{bmatrix} C_0 & C_1 & & & \\ & C_0 & C_1 & & \\ & & C_0 & C_1 & \\ & & & C_0 & \ddots \\ & & & & C_0 & \ddots \end{bmatrix}. \quad (27)$$

The form of the matrix K allows one to compute the powers of K as follows:

$$K^r = \begin{bmatrix} V(0,r) & V(1,r) & V(2,r) & V(3,r) & \cdots \\ & V(0,r) & V(1,r) & V(2,r) & \cdots \\ & & V(0,r) & V(1,r) & \cdots \\ & & & V(0,r) & \cdots \\ & & & & \ddots \end{bmatrix}, \quad r \geq 1, \quad (28)$$

with the convention that $K^0 = I$, an identity matrix of infinite dimension. From the structure of K given in Equation (27), it can readily be verified that $V(i, r) = 0$ for all $i > r$.

Using Equations (24), (26) and (27), the matrices $P(n, t)$ can be written in terms of $V(n, r)$ as

$$P(n, t) = \sum_{r=n}^{\infty} a_r V(n, r), \quad (29)$$

where $\{a_r\}$ is the probability mass function of Poisson with parameter θt . That is,

$$a_r = e^{-\theta t} \frac{(\theta t)^r}{r!}, r \geq 0. \quad (30)$$

The matrices $V(k, r)$ are computed recursively as follows:

Steps Involved in the Computation of the Matrices $V(k, r)$

Step 0. For a given, small number $\varepsilon > 0$, find n^* such that $\sum_{r=n^*+1}^{\infty} a_r < \varepsilon$. That is, n^* is the smallest index for which the sum of the tail probabilities of the Poisson with parameter θt is less than the prespecified number ε .

Step 1. Set $n = 0, V(0, 0) = I, P(0, t) \leftarrow a_0 V(0, 0)$

Step 2. $V(n, 0) \leftarrow 0, P(n, t) \leftarrow 0$, for $n \geq 1$

Step 3. For $1 \leq k \leq n^*$ and $0 \leq i \leq k$, do

$$V(i, k) = \sum_{j=\max\{0, i-(k-1)\}}^{\min\{i, 1\}} V(i-j, k-1) C_j$$

and $P(i, t) \leftarrow P(i, t) + \alpha_k V(i, k)$.

In any computational scheme, one has to have internal accuracy checks to make sure the computations are producing the desired results up to the degree of accuracy sought. In the current scheme, one can compute the exponential matrix, e^{Qt} using the uniformization method outlined earlier. Compare this matrix to $\sum_{i=0}^{n^*} P(i, t)$. These two matrices should be close (component-wise) to each other to the level of accuracy used. Another accuracy check is to compute the first two factorial moments matrices, $M_1(t)$ and $M_2(t)$, of the counting process $\{N(t)\}$ directly without the knowledge of $P(n, t)$ and compare them to the ones obtained from the computed values of $P(n, t)$ using the fact that $M_1(t) \cong \sum_{i=0}^{n^*} iP(i, t)$ and $M_2(t) \cong \sum_{i=0}^{n^*} i^2 P(i, t)$. Subject to the accuracy level, the results should agree. For direct computations of $M_1(t)$ and $M_2(t)$ we refer to Neuts [6].

The Palm Function of MAP. The Palm function, $H(t) = \alpha E[N(t)] \mathbf{e}$, and its density for the MAP process are given by [6]

$$H(t) = \lambda t + \alpha [I - e^{Qt}] (\mathbf{e} \pi - Q)^{-1} D_1 \mathbf{e},$$

$$h(t) = H'(t) = \lambda + \alpha (-e^{Qt} Q) (\mathbf{e} \pi - Q)^{-1} D_1 \mathbf{e},$$
(31)

where the initial probability vector, α , of the MAP can be appropriately chosen. Here, we take $\alpha = (\pi D_1 \mathbf{e})^{-1} \pi D_1$, so as to start the MAP at time origin with an arbitrary arrival. Note that when $\alpha = \pi$, the Palm function and its density are given by $H(t) = \lambda t$ and $h(t) = \lambda$ since $\pi e^{Qt} = \pi$ for all t .

Now we will consider the following five different MAPs, all of which have the same mean of 1. However, each one of them is qualitatively different. The first three labeled ERLANG, EXPON, and HYPEXP are all renewal processes, and their standard deviations are 0.44721, 1.0, and 2.24472, respectively; the other two labeled MAP-NC

and MAP-PC are correlated processes such that the first one has a correlation of -0.48891 and the second has 0.48891 as its correlation. Both of these correlated processes have the same standard deviation of 1.40952.

ERLANG. This is Erlang of order 5 with parameter 5. Recall that for this case D_0 and D_1 are given by

$$D_0 = \begin{bmatrix} -5 & 5 & 0 & 0 & 0 \\ 0 & -5 & 5 & 0 & 0 \\ 0 & 0 & -5 & 5 & 0 \\ 0 & 0 & 0 & -5 & 5 \\ 0 & 0 & 0 & 0 & -5 \end{bmatrix},$$

$$D_1 = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 5 & 0 & 0 & 0 & 0 \end{bmatrix}.$$

EXPON. This is exponential with parameter 1. Here, $D_0 = -1$ and $D_1 = 1$.

HYPEXP. This is the mixture of two exponentials with mixing probabilities 0.9 and 0.1, and with parameters 1.9 and 0.19. Here,

$$D_0 = \begin{bmatrix} -1.9 & 0 \\ 0 & -0.19 \end{bmatrix},$$

$$D_1 = \begin{bmatrix} 1.710 & 0.190 \\ 0.171 & 0.019 \end{bmatrix}.$$

MAP-NC. Here, we take D_0 and D_1 to be

$$D_0 = \begin{bmatrix} -1.00243 & 1.00243 & 0 \\ 0 & -1.00243 & 0 \\ 0 & 0 & -225.797 \end{bmatrix},$$

$$D_1 = \begin{bmatrix} 0 & 0 & 0 \\ 0.01002 & 0 & 0.99241 \\ 223.539 & 0 & 2.258 \end{bmatrix}.$$

MAP-PC. Here we take D_0 and D_1 to be

$$D_0 = \begin{bmatrix} -1.00243 & 1.00243 & 0 \\ 0 & -1.00243 & 0 \\ 0 & 0 & -225.797 \end{bmatrix},$$

Figure 2. Probability density functions of the MAPs.

$$D_1 = \begin{bmatrix} 0 & 0 & 0 \\ 0.99241 & 0 & 0.01002 \\ 2.258 & 0 & 223.539 \end{bmatrix}.$$

For these five MAPs, we will first plot the probability density functions. First note that the probability density functions of MAP-NC and MAP-PC are identical since the row sums of D_1 are the same for both. These graphs, given in Fig. 2, were generated using Mathematica 6.0.

A quick look at Fig. 2 reveals the qualitative nature of these MAPs even though the means are all the same. Also, the density functions of the two MAPs that have nonzero correlation are identical due to the fact that the row sums of the matrix D_1 are the same for these two processes. However, when one looks at the other features of these processes (discussed below), the difference in these two processes is noticeably clear.

The Palm function and its density for these five MAPs are displayed in Figs. 3 and 4. These were obtained using the FORTRAN code that was kindly supplied to the author by its developer, Dr. Jian-Min Li.

When looking at Fig. 3 we notice that for the three renewal processes (namely, the ones labeled, ERLANG, EXPON, and HYPExp), for every fixed t , $\ln(H(t))$ appears to increase with increasing variability. However looking at all five MAPs we cannot say the same. For example, the MAP labeled MAP-PC has a smaller variance compared to HYPExp, and yet it has the largest value for $\ln(H(t))$ for

every t among all five MAPs. A similar observation holds good when looking at $\ln(h(t))$ plot as shown in Fig. 4.

Properties of MAP. Suppose that there are n assembly lines each of which is producing items that are sent to a common area for further processing (like inspecting and packing). Let the times between the products arriving to the common area from assembly line i be modeled as a MAP with parameter matrices $(D_0(i), D_1(i))$ of order m_i . Then the times between arrivals of items to the common area (irrespective of where the items are produced) is again a MAP with parameter matrices (C_0, C_1) of order $m_1, m_2, \dots, m_n$, where

$$C_0 = D_0(1) \oplus D_0(2) \oplus \dots \oplus D_0(m),$$

$$C_1 = D_1(1) \oplus D_1(2) \oplus \dots \oplus D_1(m),$$

where the symbol $\oplus$ denotes the Kronecker sum. Given two matrices A of dimension p and B of dimension q , the Kronecker sum $A \oplus B$ of dimension pq is defined as $A \otimes I + I \otimes B$, where the symbol $\otimes$ denotes the Kronecker product and I is an identity matrix of appropriate dimension. The (i, j) th block element of the matrix $A \otimes B$ obtained as Kronecker product of A and B is given by $(a_{ij}B)$. For details on the Kronecker product and sum, we refer the reader to Ref. 9.

The output or departure process of queues plays an important role, especially in the context of network of queues. For example, in a network of queues (queues in series) the input to station 2 is nothing but the output from station 1, input to station 3 is output from station 2, and so on. The output process of many finite capacity queueing models with Markovian structure can be modeled as a MAP or batch MAP depending on the nature of services (see for example, the references listed as 72, 76, 101, 114, 115, and 116 in Ref. 10). But these suffer from the curse of dimensionality when the buffer sizes are large.

Descriptors for MAP. As mentioned earlier, one of the distinct features of a MAP process is its ability to model a variety of processes in practice, and hence MAP plays

Figure 3. $\ln(H(t))$ for five different MAPs.

Figure 4. $\ln(h(t))$ for five different MAPs.

a significant role in stochastic modeling. A natural question is how do we qualitatively compare different MAP processes? A number of descriptors have been proposed in the literature. Some of these include (i) the lower order moments that are commonly used to characterize the interarrival times (these do not capture the dependencies among the interarrival times); (ii) the dispersion curve; (iii) the peakedness; (iv) the autocorrelation of the interarrival times; (v) the index of dispersions for intervals (IDI); (vi) the index of dispersions for the counts (IDC); and (vii) the index of burstiness.

Note that the behavior of queueing models, especially when MAP is used as input process, cannot be accurately predicted based

on the first- and second-order properties of the counting process associated with the arrival process. Here, we will discuss only one descriptor, namely, the IDC and refer to the survey paper [10] on MAP and BMAP for references to other descriptors.

Index of Dispersions for the Counts of a MAP. Let $V(N(t))$ denote the variance of the counting process $N(t)$. This function for the stationary version (namely, when $\alpha = \pi$) is given by [11]

$$\begin{aligned} V(N(t)) = & [\lambda - 2\lambda^2 + 2\pi D_1(\mathbf{e}\pi - Q)^{-1}D_1\mathbf{e}] \\ & \times t - 2\pi D_1(\mathbf{e}\pi - Q)^{-1}(I - e^{Qt}) \\ & \times (\mathbf{e}\pi - Q)^{-1}D_1\mathbf{e}. \end{aligned} \quad (32)$$

The index, $ID(t)$, of dispersions for the counts of a MAP with representation (D_0, D_1) of order m defined as the ratio of the variance

$$ID(t) = \frac{V(N(t))}{H(t)} = \frac{[\lambda - 2\lambda^2 + 2\pi D_1(\mathbf{e}\pi - Q)^{-1}D_1\mathbf{e}]t - 2\pi D_1(\mathbf{e}\pi - Q)^{-1}(I - e^{Qt})(\mathbf{e}\pi - Q)^{-1}D_1\mathbf{e}}{\lambda t}. \quad (33)$$

As $t \rightarrow \infty$, the limiting index of dispersion for counts approaches a finite value and is given by

$$ID(\infty) = \lim_{t \rightarrow \infty} ID(t) = 1 - 2\lambda + \frac{2\pi D_1(\mathbf{e}\pi - Q)^{-1}D_1\mathbf{e}}{\lambda}. \quad (34)$$

Using the same five MAPs, we now display the $\ln(ID(t))$ as a function of t in Fig. 5. Observe the noticeable differences in the five MAPs under consideration and the role of the correlation (especially the positively correlated one) played in this measure as well.

Examples. We will illustrate the versatility of the MAP with a few additional examples here. First, we would like to highlight a few general observations useful in stochastic modeling. In order to compare different models (for different scenarios) properly, one has to keep the underlying characteristics of the random variable the same. For example, let $\{X_n\}$ denote the sequence of the interarrival times of a point process with a common probability function to a queueing system.

function to the Palm function and is given by (for the stationary version by taking $\alpha = \pi$)

In order to compare different arrival processes on key performance measures such as throughput or the mean time spent in the system, we would like to fix the mean and possibly the variance of X . Fixing the mean to take a specific value is very simple and requires only scaling the random variable accordingly. However, to require that this random variable also take a specific value for the variance may need more work than simply scaling it. One of the challenging aspects dealing with MAP is the number of parameters that need to be manipulated to have the required mean, variance, and possibly the correlation values.

Generally speaking, for renewal processes (used as interarrival times for a queueing system) the key measures such as throughput and the mean waiting time in the system are monotonic (either increasing or decreasing) as the variance of the interarrival times (fixing the mean to be the same for all arrival processes) increases. However, when we look at correlated arrival processes such as monotonic properties appear to not hold good. We will illustrate a few of these through the versatility of the MAP here.

Figure 5. $\ln(ID(t))$ for five different MAPs.

First we generate a MAP with representation (D_0, D_1) of order $m = m_1 + m_2$, using two PH distributions with representations (α, T) of order m_1 and (β, S) of order m_2 as follows. Take

$$D_0 = \begin{bmatrix} T & \\ & S \end{bmatrix},$$

$$D_1 = \begin{bmatrix} p_1 \mathbf{T}^0 \alpha & (1-p_1) \mathbf{T}^0 \beta \\ (1-p_2) \mathbf{S}^0 \alpha & p_2 \mathbf{S}^0 \beta \end{bmatrix}, \quad (35)$$

where p_1 and p_2 are two parameters such that $0 \leq p_1, p_2 \leq 1$ and one can play with these parameters to arrive at close to desired values for the correlation coefficient. It should be noted that for medium to large values for the correlation, the values of m_1 and m_2 may have to be large.

For this set of examples, we choose (α, T) to be Erlang of order 4 with parameter a and (β, S) to be exponential with parameter $100a$. To get MAP with negative correlation, we fix $p_2 = 0.01$ and vary p_1 from 0.01 to 0.91 with increments of 0.1; to get MAP with positive correlation, we fix $p_2 = 0.91$ and vary p_1 from 0.01 to 0.91. The values of a are chosen so that the mean for all these MAPs are set

at 1. In Table 1, we list the values of a , p_1 , and p_2 along with the standard deviations, correlations, along with (i) the index of dispersions for the count as t approaches infinity (Eq. 34), (ii) the mean waiting time in the queue of an arriving customer, μ_{WTQA} , to a MAP/M/5 (a 5-server queueing model in which arrivals occur according to a MAP and homogeneous exponential servers with a mean service time of 4.5), and (iii) P (an arrival has to wait before getting into service). We refer the reader to article titled *The G/G/s Queue* in this encyclopedia for details on multiserver queueing model.

A striking observation of the table is the fact that in the case of positively correlated MAPs, the measure $ID(\infty)$ appears to increase as the correlation coefficient increases. Note that the same cannot be said by ignoring the correlation and looking at $ID(\infty)$ as a function of the standard deviation. The mean waiting time in the queue of an arriving customer, μ_{WTQA} as well as the probability that an arriving customer has to wait to get into service, appear to increase as the correlation increases (even though the corresponding standard deviation is decreasing). This clearly demonstrates the key role played by correlation (especially the

positive one) in stochastic modeling; this is largely ignored in the literature.

Simulation of MAP. Simulating a MAP with representation (D_0, D_1) of order m is carried out as follows: For the sake of simplicity in describing the simulation process, we will write these parameter matrices as given below:

$$D_0 = \begin{bmatrix} -\lambda_1 & \lambda_1 q_{12} & \cdots & \lambda_1 q_{1m} \\ \lambda_2 q_{21} & -\lambda_2 & \cdots & \lambda_2 q_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ \lambda_m q_{m1} & \lambda_m q_{m2} & \cdots & -\lambda_m \end{bmatrix},$$

$$D_1 = \begin{bmatrix} \lambda_1 p_{11} & \lambda_1 p_{12} & \cdots & \lambda_1 p_{1m} \\ \lambda_2 p_{21} & \lambda_2 p_{22} & \cdots & \lambda_2 p_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ \lambda_m p_{m1} & \lambda_m p_{m2} & \cdots & \lambda_m p_{mm} \end{bmatrix}. \quad (36)$$

Step 0. Choose an initial probability vector, $\alpha = (\alpha_1, \dots, \alpha_m)$ for the underlying CTMC with generator $Q = D_0 + D_1$. If one is interested in simulating a stationary version, then solve for the steady state probability of Q .

Step 1. Choose a random sample from the set $\{1, 2, \dots, m\}$ with probabilities given by the components of α , generate the starting state. Let this state be denoted by i . The MAP will be in this state for an exponential amount of time with parameter λ_i . Choose a random sample from this exponential distribution. This sample determines the sojourn time of the MAP in this state during this visit.

Step 2. Choose a random sample from the discrete probability function on the set $\{1^*, 2^*, \dots, (i-1)^*, (i+1)^*, \dots, m^*, 1, 2, \dots, m\}$ with probabilities $\{q_{i1}, q_{i2}, \dots, q_{i,i-1}, q_{i,i+1}, \dots, q_{im}, p_{i1}, p_{i2}, \dots, p_{im}\}$. Let the state chosen be j .

Step 3. If j belongs to the set $\{1^*, 2^*, \dots, (i-1)^*, (i+1)^*, \dots, m^*\}$, then the MAP made a transition without an arrival and the MAP spends in state j ($j \neq i$) for an exponential amount of time with parameter λ_j . Otherwise,

there is an arrival to the system and the MAP will be in phase j , $1 \leq j \leq m$, for an exponential amount of time with parameter λ_j .

Step 4. If the desired number of samples from the MAP is taken or the simulation run time is expired, stop. Otherwise, go to step 2 by replacing state i with state visited in step 3.

Using ARENA, a powerful simulation tool developed by Rockwell Software Inc., we simulated the MAP-PC using the steps outlined in steps 0 through 4 above. The simulation was run for 100,000 units and the inter-arrival times of the simulated values are plotted along with their autocorrelation function in Fig. 6. This autocorrelation function was generated using MINITAB. One can see the closeness of the actual and fitted density functions as well as the correlations (look at the autocorrelation of lag 1 in Fig. 6b to compare with the theoretical value of 0.48891).

MAP IN DISCRETE TIME

Recall that the development of MAP in continuous time started from generalizing to PH-renewal process and on to MAP. The development of MAP in discrete time starts from generalizing the classical geometric process with discrete PH-renewal process (see **Phase-Type (PH) Distributions**).

Discrete MAP (D-MAP)

Consider an m -state Markov renewal process in discrete time $\{(X_n, J_n), n \geq 0\}$ in which each transition results in an arrival. The transition probabilities are given by

$$P\{J_n = j, Y_n = k, X_n = r | J_{n-1} = i\} \\ = [(D_0)^r D_1]_{ij}, \text{ for } 1 \leq i, j \leq m, r \geq 0.$$

Let $D = D_0 + D_1$ denote the transition probability matrix of the underlying DTMC of the D-MAP. For details on DTMC, we refer the reader to the section titled "Discrete-Time Markov Chains (DTMCs)" of

Figure 6. Simulated MAP-PC process: (a) fitted density function and (b) autocorrelation function.

this handbook. The (i, j) th entry of D_0 gives the conditional probability that in the next time unit, the MAP goes to state j with *no* arrivals given that the current state is in i . The (i, j) th entry of D_1 gives the conditional probability that in the next time unit the MAP goes to state j with an arrival given that the current state is in i . In order for a MAP to have an arrival with probability 1, it is necessary and sufficient that the matrix $(I - D_0)$ is nonsingular.

Thus, MAP in discrete time is described by the parameter matrices (D_0, D_1) of order m , whose underlying DTMC is governed by the transition probability matrix, D . Let δ be the stationary probability vector of the MC with transition probability matrix D . That is, δ is the unique (positive) probability vector satisfying

$$\delta D = \delta, \delta \mathbf{e} = 1. \quad (37)$$

Let α be the initial probability vector of the underlying DTMC governing the MAP. Then, similar to continuous-time MAP, one can appropriately choose α to model the time origin to be (i) an arbitrary arrival point; (ii) the end of an interval during which there are at least k arrivals; (iii) the point at which the system is in a specific state such as the end or beginning of a busy period. The most interesting case is the one in which we get stationary version of the MAP by $\alpha = \delta$.

The constant $\lambda = \delta D_1 \mathbf{e}$, referred to as the fundamental rate, gives the expected number of arrivals per unit of time in the stationary version of the MAP.

By taking $\alpha = \pi$, we get the stationary version for $F(\cdot)$. By taking $\alpha = (\pi D_1 \mathbf{e})^{-1} \pi D_1$, $F(\cdot)$ is the CDF of two successive arrivals in the stationary version.

Let X denote the time to the first arrival in a discrete MAP with representation (D_0, D_1) of order m . Then, the probability mass function of X is given by

$$P(X = n) = \alpha D_0^{n-1} D_1 \mathbf{e}, n \geq 1, \quad (38)$$

with $P(X = 0) = 1 - \alpha \mathbf{e}$. In most applications $\alpha \mathbf{e} = 1$ and so $P(X = 0) = 0$.

Let $\Phi(z_1, z_2)$ denote the joint probability-generating function of the first two intervals, say, X_1 and X_2 , in the MAP with initial probability vector α . Then, it is easy to verify that

$$\begin{aligned} \Phi(z_1, z_2) &= \\ z_1 z_2 \alpha (I - z_1 D_0)^{-1} D_1 (I - z_2 D_0)^{-1} D_1 \mathbf{e}, \\ 0 &\leq z_1, z_2 \leq 1. \end{aligned} \quad (39)$$

From Equation (39) one can easily obtain the means, variances, and the correlation of X_1 and X_2 , as follows.

$$\begin{aligned}
E(X_1) &= \alpha(I - D_0)^{-1}\mathbf{e}, E(X_2) = \alpha(I - D_0)^{-1}D_1(I - D_0)^{-1}\mathbf{e}, \\
V(X_1) &= 2\alpha(I - D_0)^{-2}D_0\mathbf{e} - [E(X_1)]^2, \\
V(X_2) &= 2\alpha(I - D_0)^{-1}D_1(I - D_0)^{-2}D_0\mathbf{e} - [E(X_2)]^2, \\
\rho(X_1, X_2) &= \frac{\alpha(I - D_0)^{-1}\mathbf{e} + \alpha(I - D_0)^{-2}D_1(I - D_0)^{-1}D_0\mathbf{e} - E(X_1)E(X_2)}{\sqrt{V(X_1)V(X_2)}}.
\end{aligned} \tag{40}$$

Like in the continuous-time MAP, discrete-time MAP can be described as a two-dimensional Markov process and the role of generator given in Equation (23) is played by the transition probability matrix with the same structure. The details are omitted.

The Counting Process of D-MAP

Let $\{N(t), t = 0, 1, 2, \dots\}$ denote the counting process associated with the discrete MAP with parameter matrices (D_0, D_1) of order m . Denoting by $p_{ij}(n, t) = P(N(t) = n, J(t) = j | N(0) = 0, J(0) = i)$ where $J(t)$ denotes the state of the DTMC with transition probability matrix D . Let $P(n, t)$ denote the matrix whose (i, j) th element is given by $p_{ij}(n, t)$. It is easy to verify that

$$\begin{aligned}
P(0, t+1) &= P(0, t)D_0, \quad t \geq 0, \\
P(n, t+1) &= P(n, t)D_0 + P(n-1, t)D_1, \\
n &\geq 1, t \geq 0.
\end{aligned} \tag{41}$$

The matrix probability-generating function, $P^*(z, t)$, of the process $\{P(n, t)\}$ is then given by

$$\begin{aligned}
P^*(z, t) &= \sum_{n=0}^{\infty} z^n P(n, t) \\
&= (D_0 + zD_1)^t, \\
0 &\leq z \leq 1, t \geq 0.
\end{aligned} \tag{42}$$

First, note that $P(n, t) = 0$, for $n > t$ since we are dealing with single arrivals and these occur only at discrete time points. From Equation (42) either through identifying like coefficients or through differentiation, one can derive an expression for $P(n, t)$ in terms of the parameter matrices. It can be verified that

$$\begin{aligned}
P(n, t) &= \sum_{\substack{i_1 + i_2 + \dots + i_t = n \\ i_r = 0/1, 1 \leq r \leq t}} \\
&D_1^{i_1} D_0^{1-i_1} D_1^{i_2} D_0^{1-i_2} \dots D_1^{i_t} D_0^{1-i_t}, \quad t \geq n \geq 0.
\end{aligned} \tag{43}$$

Let $M(t) = E[N(t)]$. First note that $M(0) = 0$. From Equation (41), we get the following difference equation:

$$M(t+1) = M(t)D + D^t D_1, \quad t \geq 0, \tag{44}$$

where we use the fact that $\sum_{n=0}^{\infty} P(n, t) = P^*(1, t) = D^t$. The difference equation in Equation (44) admits an explicit solution and is given by

$$M(t) = \sum_{i=0}^{t-1} D^i D_1 D^{t-1-i}, \quad t \geq 1. \tag{45}$$

For the computation of $M(t)$ it is recommended to use the recursive equation given in Equation (44) rather than the explicit expression in Equation (45). The Palm function $H(t) = \alpha M(t)\mathbf{e}$ can be evaluated depending on how the initial probability vector, α , of the MAP is chosen. If $\alpha = \delta$, the Palm function using Equation (41) reduces, as is to be expected, to $H(t) = \lambda t$. The details are omitted.

Special Cases of D-MAP

By appropriately choosing the parameter matrices (D_0, D_1) of the discrete MAP, we can get some well-known processes. Some commonly used ones are summarized here.

Geometric Process

Here $m = 1, D_0 = p, D_1 = 1 - p$, for $0 < p < 1$.

Batch PH-Renewal Process. Suppose that the interarrival times in a point process follow a discrete PH distribution with representation (β, T) of order m (see **Phase-Type (PH) Distributions**). Then this point process is a MAP with $D_0 = T$ and $D_1 = T^0\beta$.

Discrete PH Semi-Markov Process. Consider a semi-Markov process

$$D_0 = \begin{bmatrix} T(1) & 0 & \cdots & 0 \\ 0 & T(2) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & T(r) \end{bmatrix}, D_1 = \begin{bmatrix} p_{11}\mathbf{T}^0(1)\beta(1) & p_{12}\mathbf{T}^0(1)\beta(2) & \cdots & p_{1r}\mathbf{T}^0(1)\beta(r) \\ p_{21}\mathbf{T}^0(2)\beta(1) & p_{22}\mathbf{T}^0(2)\beta(2) & \cdots & p_{2r}\mathbf{T}^0(2)\beta(r) \\ \vdots & \vdots & \ddots & \vdots \\ p_{r1}\mathbf{T}^0(r)\beta(1) & p_{r2}\mathbf{T}^0(r)\beta(2) & \cdots & p_{rr}\mathbf{T}^0(r)\beta(r) \end{bmatrix}.$$

Markov-Modulated Bernoulli Process (MMBP). This is a discrete version of the MMPP. Suppose that P is the transition probability matrix of the MC that governs an auxiliary process generating the arrivals. When this MC is in state i , arrivals occur with probability τ_i and with probability $(1 - \tau_i)$ no arrivals occur. Then, MMBP arrivals are a MAP with $D_0 = \Delta(e - \tau)P$ and $D_1 = \Delta(\tau)P$, where $\Delta(r)$ is a diagonal matrix whose i th diagonal entry is given by the i th component of the vector $\mathbf{r}$.

Discrete-Time Platoon Arrival Process. A platoon process is one in which arrivals

$\{(X_n, Y_n) : n \geq 0\}$ with discrete PH distributions for the interarrivals; the conditional distribution of X_n given $Y_n = i$ is a discrete PH distribution with representation $(\beta(i), T(i))$ of order m_i and $P(Y_{n+1} = j | Y_n = i) = p_{ij}$, $1 \leq i, j \leq r$. This is a MAP with parameter matrices D_0 and D_1 given by

occur in short intervals followed by long intervals of no arrivals. This type of process is common in systems such as transportation and communications. Let the intraplatoon intervals and the interplatoon intervals be discrete PH distributions with representations $(\beta(1), T(1))$ of order m_1 and $(\beta(2), T(2))$ of order m_2 , respectively. Suppose that the number of arrivals in a platoon follows a discrete PH distribution with representation $(\beta(3), T(3))$ of order m_3 . Let $\beta_0(3) = 1 - \beta(3)e$. This platoon process is a MAP with parameter matrices D_0 and D_1 given by

$$D_0 = \begin{bmatrix} T(2) & 0 \\ 0 & I \otimes T(1) \end{bmatrix}, D_1 = \begin{bmatrix} \beta_0(3)\mathbf{T}^0(2)\beta(2) & \beta(3) \otimes \mathbf{T}^0(2)\beta(1) \\ \mathbf{T}^0(3) \otimes \mathbf{T}^0(1)\beta(2) & T(3) \otimes \mathbf{T}^0(1)\beta(1) \end{bmatrix}.$$

CONCLUSION

MAP is truly a versatile point process that has found tremendous practical applications in production and manufacturing, computer and communications, and transportation systems. MAP enables one to capture the realistic assumptions as much as possible and provide solutions that practitioners can implement. Invariably models involving MAP need to have algorithmic aspects built into them to make them useful for

practitioners. Hence, it is imperative that researchers who want to get into learning and using MAP should also incorporate the algorithmic aspects as part of their routine analysis. For additional information on MAP we refer the reader to review papers [4,10], books [1,6,12,13], and the paper by Ramaswami [14] dealing with the versatile point process as input to a single server queue with general service times. For latest developments in MAP, we refer the reader to the series of *Proceedings of the International*

Conferences on Matrix-Analytic Methods in Stochastic Models [15–20].

MASS CUSTOMIZATION

ALI K. PARLAKTÜRK
JAYASHANKAR M. SWAMINATHAN
Kenan–Flagler Business School,
University of North Carolina,
Chapel Hill, North Carolina

WHAT IS MASS CUSTOMIZATION?

Mass customization can be defined as producing goods and services to meet individual customer's needs with near mass production efficiency [1]. This term was coined to parallel mass production that relied on producing large volumes of identical products like the Ford Model T line. The fundamental difference between mass production and mass customization is in the amount of product variety that is enabled by the process. Pine popularized this concept in the 1990s [2]. Over the years, it has been popular to claim that a firm provides high degree of variety in offerings, therefore the term *mass customization* has been overused.

Customization is everywhere—it is the degree of customization and the way it is offered that may be different. Automotive firms allow limited customization of individual cars through bundled options like air conditioning and leather are offered typically with an automatic transmission; Burger King offers “Have it your way” burgers that enable customers to selectively customize ingredients in their burgers; Dell computers and other electronics manufacturers successfully adapted customization to enable customers to pick and choose the key modules (such as memory, disk drive, chipset) that are associated with the computer; Sun Microsystems Java applets as well as the more popular Apple iPod and iPhones take this customization to the next level wherein the hardware is identical, but the software components (applets or iTunes files) are chosen by the customer according to their choice; the Build-A-Bear experience wherein the customer

cocreates the bear and clothing of choice is another example of customers actively involved in the customization process. There are three types of mass customization.

- *Cosmetic.* A popular approach is to customize aesthetic design of the product such as color, label, packaging, and so on. For example, M&M's (www.mymms.com) can be customized to have a personalized message, picture, and packaging. Cosmetic customization is especially popular in apparel and footwear. One example is Nike's custom-colored sneakers, which also allows the customer to imprint a name on the shoe. Nike's customization initiative is called NikeID. Customized sales accounted for 20% of the sneakers purchased from Nike.com in 2002 [3]. Another example is Zazzle offering shirts, shoes, hats, ties, and so on, with custom colors, embroidery, as well as imprinted images [4].
- *Physical Fit.* Customized physical fit can be achieved by individually customizing measurements of the product for each customer. Examples include mi adidas, Land's End, and Andersen Windows. In the mi adidas example, width, length, and insole of the shoe are customized based on the the 3D scan of the customer's foot [5]. Interestingly, an analysis of the order data shows that more than 40% of the orders are placed with different sizes for the right and left shoe [6]. Land's End, which sells custom shirts and pants, does not use 3D scanners; it asks customers to take their own measurements along with other questions about their body shape and then it relies on an algorithm fitting software developed by Archetype Solutions that finds the closest match in the extensive database of typical sizes [7]. Likewise, Andersen Windows can build a window to fit any size. Offering customized physical fit becomes more challenging

when it involves more spatial dimensions [8]. Note that customized physical fit in apparel and footwear usually requires customization along three dimensions. A number of companies either gave up their customization initiatives or went bankrupt. Examples include Levi's original spin initiative and Customatix [9], which went bankrupt selling customized sneakers.

- *Features.* Firms can also customize functional features of the product. These firms take advantage of the modular product architecture and allow customer to choose from many options for each module enabling vast number of choices for the end product. For example, Dell builds custom laptops where the customer gets to choose features like memory, hard drive capacity, CPU speed, and multimedia options. Similarly, carmakers let customer choose from various features, which can be added to the car on the basis of the customer's preferences.

Note that these three types of customization are not mutually exclusive.¹ A firm can customize its product in more than one way. For example, in addition to customized features Dell provides cosmetic customization by allowing personalized laptop covers with many different color and pattern options. Similarly, mi adidas also offers cosmetic customization allowing personalized colors and imprints on its sneakers in addition to customized physical fit. While many of the examples above are from the business to consumer segment, a large number of examples are available from the business to business segment as well. For example, Xilinx's field programmable gate arrays (FPGA) allowed customers to burn and change the circuit on the chip much later in the process. Similarly, Dell created customization in their sales process for individual business customers through customized web pages as well as staff (more examples in Ref. 13).

¹Also note that other taxonomies for mass customization are possible; for example, see Refs 10–12.

BENEFITS OF MASS CUSTOMIZATION

A firm's ability to offer mass customized products leads to a number of marketing and operational benefits.

Pricing Advantage

Mass customization creates value for customers by providing products that better match their individual preferences. This allows charging a price premium for custom products. For example, Nike is able to add 10–20% price premium for its customized sneakers that allows for custom colors and personalized imprint [3]. Adidas offers a higher degree of customization, it allows customized fit in addition to customized colors and imprinted names, and this in turn enables charging a higher 30–50% price premium [6]. In general, products that require matching physical dimensions often allow a higher price premium than products that customize just on design patterns. A customer survey on customized footwear shows that more than 50% of customers are willing to accept a price premium of 20–30% on average for custom shoes [14]. Furthermore, because mass customization allows a vast number of product versions, it enables implementing a finer price discrimination. For example, Time 121 (www.121time.com) produces custom-made Swiss watches with many modular customization options. It uses a modular pricing approach, pricing each component differently, which allows creating a product that matches more closely each customer's willingness to pay.

Mass customization also helps a firm avoid competing solely on the basis of price. Offering individually customized products enables a firm differentiate itself from its competition. A firm can offer unique attributes that cannot be directly compared to standard product alternatives (see Ref. 15 for a discussion of competition between firms following mass customization and mass production). In particular, mass customization can be a successful strategy against low-cost overseas manufacturers, as they have limited customization capabilities due to the distance from the market. Indeed, mass customization is recognized as a strategy followed by a

variety of domestic industries to fight the outsourcing of production to low-cost overseas manufacturers [16–18]. The US furniture industry is one example: US manufacturers are more successful against imports in market sectors where they offer more customization [19]. Other examples include the EU apparel industry [16] and footwear manufacturing in Finland [20].

Customer Loyalty

Customization is information intense in that a customer needs to communicate her preferences to the service provider. The firm gets into a learning relationship [21] with its customers, which increases the revenue from each customer through repeat purchases and related sales. Mass customization helps establish stronger relations with customers and gain customer loyalty. For example, when ordering a custom shirt from Lands' End [22], a customer needs to specify many physical measurements in addition to the preferred style choices. Similarly, in the case of mi adidas, the customer's feet need to get scanned to achieve customized fit. This is in addition to customers describing their style choices. In both examples, the customers can reorder with ease from the same company. Even when a customer prefers a shirt of different style, Lands' End can easily pull up the measurements from the previous order. In contrast, if the customer wants to order from a different company, she again needs to go through the process of supplying information for product customization. With mass customization, the customer invests effort to understand the firm's customization offerings and communicate her preferences, which serve as sunk costs that increase the customer's *switching costs* [23]. Furthermore, the stronger relationship established and higher levels of information acquired provide more opportunity for related sales. Thus mass customization helps build customer loyalty. The most recent example of Apple iPhone is a good one. While the sleek looks and the touch screen got the initial attention of the customer base, most of the iPhone customers rave about the application features that does small tasks such as fetching

weather, rating restaurants, finding bank information, and teaching small sentences in new languages. More importantly, no two iPhones are likely to have the same application set—demonstrating the fact that each customer's need is unique and the platform provides an opportunity for completely customization. The net result is that iPhone customers are more likely to be loyal customers.

The customer becomes coproducer of the product with mass customization. This experience itself can create additional value on top of the value of a custom product. For example, the Build-A-Bear workshop lets its customers create their custom teddy bears and other stuffed toy animals. First, the customer selects her unstuffed bear and then brings it to the stuffing machine where she gets to watch her chosen stuffing material put into the bear. This includes the memorable heart ceremony where the customer gets to choose a heart, make a special wish and place it inside her stuffed bear. The customer also gets to choose from various outfits and accessories to personalize the stuffed bear to her liking. Another example is create your own food style restaurants such as Fire and Ice (www.fire-ice.com) where the customer gets to choose the ingredients and sauces and a chef cooks the food to customer's liking. In both of these examples, the customers attain value from the customization process in addition to the end product. Note that because the customer is the coproducer of the product, he/she will have a higher tolerance and is more likely to like the product.

Better Market Understanding

In the early nineties, when Dell's computer business showed strong growth, one of the main reasons that was cited for the growth was the loyalty shown by their business customers whose needs were met more closely by Dell in comparison with its competitors. Dell accomplished this by creating individually customized web pages for each of their clients. Such an effort enabled Dell to get a better understanding of customer needs and preferences. Letting each customer design the product to her liking allows the

firm observe a more accurate reflection of customer preferences. By aggregating these observations the firm can generate better market research information without incurring any traditional market research cost. This is especially valuable for firms that also sell standard products. Indeed, most firms that offer custom products also sell standard products and they need to decide the design of products in their standard product line. In these examples, mass customization can make it possible to improve the design of standard products to better match the needs of customers. One firm that took advantage of these synergies between mass production and customization is P&G. Through its subsidiary Reflect, P&G offered customized cosmetics where customers created their own cosmetic line, mixing and matching various options like colors, scents, and skin-care preferences.² Reflect had sold nearly 10 million customized items since its launch [24]. Matching the customized order specifications with sociodemographic profile of customers and their feedback or change of specifications after the sale provided invaluable market information, which can then be used to improve the standard product offerings [23].

Better market understanding resulting from mass customization can also be very helpful for identifying trends in the marketplace and responding to them sooner. For example, when many of Dell's customers choose large-capacity hard disks in their customized configurations, Dell understands that the demand for large-capacity hard disks will go up and it can strike deals with its suppliers before the competitors notice this trend.

Reduced Inventories

An important operational benefit of mass customization is that it allows operating make-to-order as opposed make-to-stock. Because customers receive individually customized products, they are willing to

wait to some extent for their custom orders. A classic example in this regard is the European Delivery Program of BMW, where the long wait for delivery is offset by the fact that the car is built according to specifications and the customer gets a chance to pick it up from Europe.³ Industry analysts estimate that if the US car makers were to operate on a build-to-order basis that would translate to cost savings of \$3600 for each car and \$65–80 billion per year for the entire industry [26]. Avoiding carrying inventory helps avoid costs associated with inventories. For example, Dell [27] operates with less than 4 h of work in process inventory and practically no finished-goods inventory. This leads to significant savings in inventory-holding costs; furthermore, this also eliminates the forecasting risks, which are especially important for technology and fashion products. Retailers sell more than one-third of their inventory at discounted prices mainly either because of having too many items or because of stocking unpopular items [28]. Furthermore, inventory of technology products are prone to devaluation and obsolescence. The make-to-order model also has a cash flow advantage as goods are sold and at least partially paid for before they are produced. Moreover, the fact that the customers tolerate waiting for a customized product allows a firm to sell the product without even touching it as in Lands' End; in this case, the product is produced and distributed by third parties [22].

As discussed above, there are some important benefits of mass customization. However, mass customization is not for everyone. Zipkin points out that mass customization imposes special requirements for information elicitation, process flexibility,

²P&G decided to close Reflect in June 2005 and continue its mass customization initiative under its own brands such as Cover Girl [24].

³However, one needs to be careful with customization delays. A survey of manufacturing firms [25] that adopted or were considering mass customization found that delay was viewed as an important shortcoming of mass customization. For some products, customers may not have too much tolerance for delay, indeed this is one of the main reasons that few US consumers (7% in 2000) order custom cars [26].

and logistics, and many product markets are not attractive for mass customization [8]. Companies like Mattel and Levi Strauss have experimented with mass customization and abandoned these initiatives, and a number of companies went bankrupt selling customized products. Pine [2] identifies conditions under which mass customization is attractive vis-a-vis mass production. Mendelson and Parlakturk [15,29] characterize some operational and market characteristics that make mass customization attractive.

ENABLERS OF MASS CUSTOMIZATION

One of the key issues related to mass customization is that in most situations it leads to greater variance in operations and difficulties in predictability [30]. This inability to predict well leads to worse performance and hence leads to additional cost. While many firms tend to increase the price for a customized product or service, sometimes operating costs outweigh any benefits that a firm may have gained in pricing a highly customized product or service. This is one of the main reasons that mass customization in its extreme form is not widely prevalent in industry [30]. It is important to address this challenge in order to successfully implement mass customization.

Standardization Techniques

In mass customization, variability could be introduced in different ways. The most common types of variability that are associated include variability in demand both in terms of quantity and timing of orders, variability in terms of processing times since each order is different, and variability in customer knowledge and ability to participate in the cocreation of products and services. These variabilities make it difficult to operate efficiently. One way to address this is through standardization techniques. Swaminathan [30] describes four common standardization techniques, namely, process standardization, product standardization, part standardization, and procurement standardization.

Process Standardization. Process standardization (also called *postponement* or *vanilla box approach*) refers to standardizing the initial steps in the process delivery and stocking inventory at that point. Such inventory is utilized to customize individual orders that come in. The key trade-off in postponement is the ability to respond quickly and effectively to individual customization needs while optimizing the amount of additional investments in the form of semifinished inventory; Refs 31–33 provide an extensive survey of research and results on postponement while Venkatesh and Swaminathan [13] provide a rich set of real success stories and managerial implications of adopting postponement.

Product Standardization. Product standardization refers to reducing the amount of products that are actually available for the customer to buy even though on paper it might appear that everything can be customized. This way the firm is able to reduce the amount of internal variability that is created. In such situations, the firm should either price their unique products higher or quote a longer than normal lead time for delivery. This is also called *reduction* by Frei [34] in that the menu of offerings is reduced.

Part Standardization. Part standardization refers to standardizing components in the product platform; therefore, while providing high degree of variety and customization, the firm could still benefit from economies of scale on these basic components. Clearly, adopting part standardization has its negative implications as well. It is important that a customer does not perceive that level of commonality between its premium and low-quality product. However, if done right, the economies of scale and the associated innovation on parts could significantly improve the overall product and lead to higher sustained quality in such products [35]. Many successful firms such as Honda and Sony utilize part and platform standardization as an integral part of their operations strategy.

Procurement Standardization. Procurement standardization refers to creating

synergies across various components and services a firm might be buying. This is often overlooked in large organizations that grow into very independent smaller organizations that have separate procurement arms. For example, GM, in the early nineties, went through a significant change in its procurement strategy by making it more centralized and by standardizing parts and procurement across many of its product lines. This enabled the firm to cater to multiple segments in the market while obtaining synergies in procurement.

Technology Solutions

Firms can also take advantage of various technology solutions to overcome the challenges of mass customization. An important enabler is flexible manufacturing systems, which reduces the trade-off between variety and productivity. Mass customization requires the production to switch between different product versions rapidly and frequently; flexible manufacturing systems make this possible without significantly increasing the costs. Firms offering custom-fit footwear and apparel such as mi adidas and Brooks Brothers use 3D scanner technology to elicit customers' measurements, while Land's End relies on software technology running a series of algorithms that can identify a person's body size by taking just a few of his or her measurements along with questions about his or her body shape and then running them against a huge database of typical sizes. This helps create a custom fit for each customer. Companies like Amazon are able to make personalized offers taking advantage of data-mining capabilities. Amazon's recommendation engines process vast amount of information collected not only from the targeted customer but also from other customers with similar profiles. Another strategy is to provide customization through customized software while keeping the hardware identical, as in the examples of iPod and iPhones. Here, the product is decoupled into hardware and software and customization is achieved by customizing the software, which is relatively easier. In these examples, customers can add software components and content to customize the

functionality of the product on the basis of their preferences.

Involving Customers

Finally, another way to manage mass customization is to cocreate the product or service along with the customer [36]. This provides an opportunity to utilize customer labor, which can result in lower costs for the firm. For example, in the case of Fire and Ice restaurants, the customer fills a bowl with her selected vegetables, meats, and sauces, which is then cooked to the customer's liking. Here, the customer prepares the meal herself by adding the ingredients and bringing it to the centralized grill and after it is cooked, the customer carries food to her table. All these enable the restaurant avoid much of the needed labor. From the perspective of the customer, she is getting a highly customized product, while from the perspective of the restaurant, it is operating highly standardized processes, that is, replenishing ingredient bins and cooking the food brought by customers. This is possible because the customer is an integral part of the customization. Zazzle also takes advantage of greater customer involvement. Zazzle provides a platform that allows its customers to design their custom line of merchandise including T-shirts, ties, hats, mugs, shoes, and so on. The customer decides what to include in her shop (called a *gallery*) and she can customize the products by adding custom images and texts. The customer then gets a commission when another customer orders a product from her gallery. Zazzle does the order fulfillment. In this case, tasks with higher variability are done by customers whereas tasks performed by Zazzle.com have less variability. The customers design the products to be included in their stores, for other customers to buy. The products differ only in the images imprinted on them, so the production can be standardized to a great extent. Similar examples include Cafepress and Threadless.

OR/MS MODELS OF MASS CUSTOMIZATION

Mass customization is attracting increasing interest in the OR/MS literature

[15,29,37–40]. In the following, we review some of the analytical models used in these studies. Mass customization aims to eliminate each customer's sacrifice from her ideal choice by providing individually customized products. This is captured through the classical Hotelling model [41] where differences in customers' tastes are represented by their locations on the unit interval. Each product type also maps to a point on the unit interval. When a type- θ customer buys product type ζ at price p , her utility is equal to

$$U(\theta, \zeta, p) = w - p - r|\theta - \zeta|, \quad \theta, \zeta \in [0, 1], \quad (1)$$

where the reservation price $w > 0$ is the customer's willingness to pay for her ideal product and $r > 0$ is the intensity of customer preference. Mass customization enables a firm eliminate the customer's disutility by adjusting its product type to match the customer type. This framework allows studying the competition between standard and custom products [15,39,40]: firms selling standard products choose fixed locations on the unit interval (i.e., their product configurations), whereas firms selling a custom product can match any point on the interval.

There are important differences between the operations of traditional and customizing firms. A traditional firm usually carries inventory and fulfills customer demand from stock. In contrast, a customizing firm does not carry finished-goods inventory because it makes to order. Mendelson and Parlakturk [15], Xia and Rajagopalan [40], and Alptekinoglu and Corbett [42] add a delay cost to Equation (1), which is proportional to the delay customer experiences before getting her customized product. Mendelson and Parlakturk [15], Alptekinoglu and Corbett [42] model make-to-order production as an $M/M/1$ queue with higher congestion resulting in longer delays for the customers. Mendelson and Parlakturk [15], Jiang and Lee [38], and Alptekinoglu and Corbett [42] also include holding costs for standard products, which reflect the inventory cost advantage of customized products.

While the above models of mass customization are very important for developing

insights on the problem and developing strategies around product offering, yet another of the set of OR/MS models can be useful for practical operations for mass customization. These are two-stage stochastic models where, in the first stage, the firm may decide on the variants of the products to be offered and the inventory of semifinished products or parts to be stocked, while in the second stage, the firm decides how to allocate the inventory and capacity to meet the demand for customized products. While Swaminathan and Tayur [32] and Lee and Tang [43] provide details on specific models where inventory is stored as semifinished products, a much broader set of such stochastic models of this kind that are related to mass customization are discussed in Refs 33 and 44.

CONCLUSIONS

In summary, there is a growing demand for products that better match customers' individual preferences. With mass customization, the firms aim to provide each customer with his/her ideal product rather than proliferating the marketplace with product versions and hoping that customers find products that are close enough to their ideal choices. Firms mainly offer three types of customization: (i) Firms can customize appearance of the product involving colors, labeling, and so on; (ii) they can customize physical fit of the product such as customizing width, length, and insole of a sneaker; or (iii) finally, firms can customize functional features of the product adding on options that the customer chooses. There are a number of benefits that makes mass customization attractive. This includes ability to charge price premiums, establishment of stronger relations with customers, better market understanding as a result of directly observing customers' preferences, and cost savings due to operating without finished-goods inventories. While mass customization results in many benefits, it leads to some challenges due to the variability it induces to a firm's operations. To overcome these challenges, a firm can use standardization techniques such as product, part,

and procurement standardization. It can use technology enablers like flexible manufacturing systems, 3D scanners, and software technologies and finally, it can take advantage of greater customer involvement, which gives the opportunity to pass some of the task complexity on to customers.

MATERIALS REQUIREMENTS PLANNING

W.C. BENTON, JR.
Department of Management Sciences,
Fisher College of Business, The Ohio
State University, Columbus, Ohio

INTRODUCTION

Materials requirements planning (MRP) was developed specifically to assist companies in managing dependent demand inventory and scheduling replenishment orders. Specifically, MRP is a computerized *information system* that creates planned orders for both manufactured and purchased materials. The logic of the MRP (dependent demand) approach is significantly different from reorder point (ROP) (independent demand) approach. MRP has been shown to be beneficial to a variety of manufacturing companies.

In order to manage the various types of inventories for a manufacturing operation, attributes of the items must first be analyzed in terms of cost, lead time, past usage, and the nature of demand. The nature of demand is perhaps the most important attribute. The nature of demand can be either independent or dependent. *Independent* demand is unrelated to the demand for other items. In other words, an independent item must be forecasted independently. *Dependent* demand is directly derived from the demand for another inventoried item. In manufacturing firms, demand for raw materials, components parts, and subassemblies is dependent on the demand for the final item. Thus, dependent demand should not be forecasted independently. As an example, a completed automobile is an independent demand item that is forecasted. However, we know that each automobile requires a product structure for which it would make no sense to forecast the demand for wheels

independently, simply because the wheels are dependent and their demand is derived from that for the automobile. Inventory management for dependent items is usually managed by MRP. In distribution firms, demand is usually *independent*. The order quantities for each inventory item should be forecasted separately. Stock replenishment in independent demand systems is usually determined using statistical inventory control or order-point systems. The characteristics and examples of the types of demand and the types of inventory control systems are given in the text that follows.

Types of Demand

1. Independent demand characteristics and examples:
 - automobiles, televisions, and computers
 - demand often occurs at constant rate
 - effects inventories that are managed separately from other items (e.g., finished goods made-to-stock)
 - demand is managed based on forecasts.
2. Dependent demand characteristics and examples:
 - most raw materials, components, and subassemblies
 - demand is managed based on plans [e.g., master production schedule (MPS)]
 - effects inventories that are managed to support production of other items (e.g., component parts)
 - demand often occurs in lumps.

Types of Manufacturing Control Systems

Reorder Point Inventory Control System. The ROP system is based on independent demand concept. Independent demand inventory is not directly related to the internal manufacturing operation. A flow diagram of an independent demand system is given in Fig. 1.

Figure 1. Flow diagram for the reorder point inventory system.

ROP systems are driven by historical data to forecast future inventory demand. The forecast assumes that past data are representative of future demand. As shown in Fig. 1, if at any time an item's inventory level falls below some predetermined level, either additional inventory is ordered or new production orders are released in fixed order quantities (FOQ). Although most early ROP systems were manual, automated ROP systems soon followed when commercial computer use increased in the 1960s.

Evolution from ROP Inventory Control to MRP Systems. During the early 1970s computerized MRP systems began to replace ROP systems as the preferred manufacturing control system. MRP systems presented a clear advantage in that they offered a forward-looking, demand-based approach for planning the manufacture of products and the ordering of inventory. This approach allowed lumpy inventory levels experienced under ROP's FOQ capabilities to be smoothed

and managed more effectively under MRP's more precise time-phased order-generation capabilities. In addition, MRP systems introduced basic computerized production reporting tools that could be used to evaluate the viability of the master schedule against projected materials demand.

MRP is a computer-driven information system that translates end item demand from the master production schedule into time-phased requirements for raw materials, component parts, and subassemblies, working backward from the due date using lead times, lot sizes, and other relevant production information. The MRP system is different from the ROP manufacturing planning and control. Prior to the introduction of MRP in the early 1970s, variations of the ROP system were used to plan and control production inventories. The MRP system makes it possible to construct a time-phased requirement record for any part number. The MRP logic also allows for detailed capacity planning models. Developing the requirements plan (materials and capacity) is basically an iterative process, where the planning is executed level by level. For example, planning for a tractor would determine requirements for tires, transmission, bucket size, and so on. However, planning for tires has to be done after the planning for wheels. Suppose the company planned to build 40 tractors and each tractor requires four wheels, then 160 wheels will be required. If 100 wheels are currently on hand and 20 wheels have already been ordered, only 40 more wheels must be ordered to complete the 40 tractors. An illustration of the MRP lot-sizing approach for time-phased requirements is given in the next section.

MRP LOT SIZING

The general lot-sizing problem for time-phased requirements for a component part involves converting the requirements over the planning horizon (the number of periods into the future for which there are requirements) into planned orders by batching the requirements into lots. The specific method for determining the order quantities for a component part is given by a lot-sizing procedure. In many cases, the lot-sizing procedure

Table 1. Net Requirements for 12 Periods

Period	1	2	3	4	5	6	7	8	9	10	11	12
Net requirements	80	100	124	50	50	100	125	125	100	100	50	100

Order cost = \$92, inventory carrying cost = \$0.5/period/unit.

performance is based on the minimization of the sum of ordering and inventory carrying costs subject to meeting all requirements for each period. An ordering cost is incurred for each planned order placed. A carrying cost is charged against the ending inventory balance in each period. The sum of these two cost components is the total inventory cost.

Lot-sizing procedures evaluate orders that cover the requirements for one or more periods. For example, in Table 1, a minimum of 80 units must be ordered for period 1 (to meet that period's requirement), but other alternatives would include an order of 180 (for the first two periods' requirements), 304 (first three periods' requirements), and so on.

In order to avoid being out of stock, there must be an order received in the first period in which there is a requirement not covered by inventory (net requirement). In order to fill the first net requirement, the firm will incur the cost of ordering (all costs associated with placing and receiving an order). It may be less expensive to combine the first net requirement with another requirement and hold the additional units in inventory until they are needed rather than pay for another order. Additional net requirements for periods beyond the first should be included as long as the cumulative units, times the number of periods to be held, times the cost to hold a unit for one period, are less than or equal to the order cost. When this is no longer true, placing another order is less costly. In general, this is the criterion used to establish the purchase order quantity for the lot-sizing procedures. The MRP concept is illustrated in the example briefly below. A more comprehensive discussion is given in the article *Lot-Sizing*.

For components of assembled products, the demands are not usually constant per unit time, and depletion is anything but gradual. Inventory depletion for component parts tends to occur in discrete "lumps" because of the lot sizing of the final product.

Requirements dependent on the final product are usually discontinuous and lumpy since requirements for these components depend on when the product is built. In some periods, there may be a few or no component requirements, and in the next, a requirement for many will occur. As an example, Table 2 shows a case in which customer demand is fairly uniform but, because of the build schedules, the requirements for the components are "lumpy." The build schedule shows periods of zero requirements before a requirement of 50 component parts is encountered. This requirement sequence, very common to component parts, is not handled well with the non-time-phased ROP techniques.

With the ROP system, the production control manager does not plan for future requirements but reacts to the current situation, which may require expediting to prevent a materials shortage. In these situations, expediting is used as a substitute for planning future requirements. An improved basis for planning to meet future needs would be to extend the requirement information throughout enough time periods to cover the entire manufacturing lead time. This provides the time-phased requirement information that is the basis for MRP systems.

MRP systems utilize substantially better information on future requirements than is possible by the non-time-phased ROP systems. MRP systems are helpful for

Table 2. An Example for Lumpy Requirements

Periods	1	2	3	4	5	6	7	8
Projected customer demand	15	15	15	10	15	10	10	10
Build schedule				50				50
Component requirements			50				50	

On hand = 50 units, safety stock = 5 units, lead time = 1 period.

companies with assembled products that have component requirements dependent on the final product. The system provides information to better determine the quantity and timing of component parts and purchase orders than is possible with the non-time-phased ROP systems.

MRP BASICS

The MRP concept provides the basis for projecting future inventories in a manufacturing operation. MRP can help improve the traditional non-time-phased order-point system because it allows the operating manager to plan requirements (raw material, component parts) to meet the final assembly schedule. In other words, MRP provides a plan for component and subassembly availability that allows certain end products to be scheduled for final assembly in the future. Once a firm's final assembly schedule has been determined and the product bills of materials have been finalized, it is possible to precisely calculate the future materials needs for the

final assembly schedule. The product bill of materials for a given finished product can be broken down, or "exploded," and extended for all component parts to obtain that product's exact requirements for each component part. The MPS sets out an aggregate plan for production. MRP translates that aggregate plan into an extremely detailed plan. An overview of the MRP system is illustrated in Fig. 2.

MRP Inputs

The MRP inputs include the MPS, the bill of materials (BOM) file, and the inventory records file.

1. *Master Production Schedule (MPS)*. The MPS is the anticipated build schedule that is derived from forecasted demand and actual customer-booked orders. The MPS is the exact time-phased build schedule needed to satisfy booked orders and forecasted demand.
2. *Bill of Materials (BOM)*. The BOM is a list of all of the raw materials, parts, subassemblies, and assemblies needed

Figure 2. An overview of MRP.

to produce one unit of a product. The computerized MRP system processes the BOM file from left to right starting with the highest or zero level. Sub-assemblies and parts that go directly into the assembly of the finished product are called *level 1 components*. The parts and components that go into the assembly items are level 2, and so on. The MRP explosion involves determining the quantity and lead time for each item required to satisfy the item at that level. The results of the BOM explosion process are a time-phased requirement for specific quantities of each item necessary to assemble the finished product.

3. *Inventory Records File*. The inventory records file contains specific information on the quantity of each item on hand, on order, and committed to use in future time periods. The MRP gross to net processing logic determines the quantity available for use in a given period, and if enough are available to meet the order requirements, it commits these for use during the time period by updating the inventory record file. If there is not enough of the item available, the system includes the item order information (e.g., lot size, lead time, and scheduled receipts). A planned order release is then initiated.

MRP Outputs

The MRP outputs are the order action report, the open order report, and the planned order release report. The order action report shows which orders are to be released during the current time period and which orders are to be canceled. The open order report shows the orders that are to be expedited. The planned order release report is the time-phased plan for orders to be released in future periods. The secondary output reports are performance-control reports, planning reports, and exception reports.

The Basic MRP Record

The basic MRP record is given in Table 3. The explanation for each row is as follows:

Table 3. Time-Phased MRP Record

	Week											
	1	2	3	4	5	6	7	8	9	10	11	12
<i>J750 Engine Assembly Master Schedule</i>												
Quantity												
<i>Turbine housing requirements</i>												
Gross requirements												
Scheduled receipts ^a												
Projected available ^b												
Net requirements												
Planned order release												

^aMeasured at the end of each week.

^bReceived at the beginning of each week.

- *Gross Requirements (GRs)*. The gross requirement (GR) is the total quantity needed for an item on a weekly basis. It is assumed that the quantity will be available on Monday morning for the week in question.
- *Scheduled Receipts (SRs)*. The scheduled receipts (SRs) are orders that have already been launched, either as a shop order or purchased item. Scheduled receipts are important because they represent a commitment of resources. It should be assumed that the exact quantity and timing of these orders are certain and that the orders will be delivered in the expected period.
- *Projected Available (PA)*. The projected available (PA) is the inventory of the component at the end of the week.
- *Net Requirements (NR)*. The net requirements are the amount of the inventory item needed for the week after the GRs have been netted against available inventory and SRs.
- *Planned Order Releases (PORs)*. The planned order releases (PORs) are the quantities of net requirements that are planned to be ordered in the beginning of the period, taking into account lot sizes and time-phasing. Unlike SRs, PORs are not firm orders. The PORs are the primary outputs of the MRP system, as they represent the expected timing and quantities of future purchases and production plans.

Figure 3. An overview of MRP II.

Manufacturing Resource Planning II (MRPII)

MRP II involves integrating the computerized MRP systems with financial planning, marketing, engineering, purchasing, and other functional areas. There are a number of MRP II software packages available for implementation. An overview of an MRP II system is shown in Fig. 3.

EXAMPLE FOR MRP¹

The production control manager at Point Clear, Inc. decided to implement a time-phased requirements planning (MRP) system. In May, he had attended a short course on world-class manufacturing. He now needed to convince the plant manager that requirements planning could work for Point Clear's jet engine assembly operation. The production control manager decided that a simple example was needed to illustrate his ideas.

He first prepared a master schedule for one of the engine types produced by Point

Table 4. J750 Engine Master Schedule

	Week											
	1	2	3	4	5	6	7	8	9	10	11	12
Quantity	75	25	35	50	0	45	100	50	0	40	10	80

Clear—the J750 turbo engine. The resulting master schedule is shown in Table 4. This 12-week schedule shows the number of units of the J750 engines that had to be assembled. He also decided to consider two “A” items to represent the projected requirements for the J750. The two “A” items were representative of the many other components. These two components, the turbine housing and the 562 turbine assemblies, are shown in the product structure diagram in Fig. 4. The production control manager noted that the turbine auxiliary power unit is purchased from a tier one supplier and is shipped to the main engine assembly plant. The manufacturing stages that are involved in producing a J750 involve the engine assembly department and the auxiliary power unit.

The manufacturing and purchase lead times required to produce the turbine housing and the turbine assembly components

¹Abbreviated from core study in Benton, 2010.

are also indicated in Fig. 4. Note that two weeks are required to fabricate the turbine housings and that all of the turbine housings must be delivered to the engine assembly plant before Monday morning of the week

in which they are to be used. It takes three weeks to produce one lot of turbine assemblies, and all of the assemblies that are needed for the production of turbine housings for a specific week must be delivered to the

subassembly department stockroom before Monday morning of that week. The BOM and economic data for the Point Clear case example are shown in Fig. 5.

In preparing the MRP example, the following assumptions are made:

1. Eighty-five turbine housings are on hand at the beginning of week 1 and 25 turbine housings are currently on order to be delivered at the start of week 2.
2. Two hundred turbine assemblies are on hand at the start of week 1 and 120 are scheduled for completion at the beginning of week 2.
3. Point Clear is currently ordering using the lot-for-lot (L4L) method. The period-order-quantity (POQ) method will be compared with the L4L ordering method.
3. Twenty-five turbine housings are scheduled to be received in week 2.
4. Two hundred turbine assemblies are on hand at the beginning of week 1.
5. One hundred and twenty turbine assemblies are scheduled to be received in week 2.
6. The BOM is as given in Fig. 5.
7. Costs for each assembly are as given in Fig. 5.

The following are the alternatives:

- Order using L4L (see Table 5).
- Order using the POQ method (see Table 6)

See the lot-sizing entry on page_ for a more comprehensive discussion on lot sizing.

Solution to the Point Clear engine company MRP Example

The data pertaining to Point Clear are as follows:

1. There are no capacity issues.
2. Eighty-five turbine housings are on hand at the beginning of week 1.

LIMITATIONS OF MRP

At a glance, MRP appears to be technically robust. However, the implementation of MRP is fraught with many problems. The source of the failures of MRP can be traced to both organizational and behavioral factors. The primary factors responsible for MRP failure are: (i) the lack of top management commitment; (ii) the failure to realize that MRP

is merely a computer program that requires accurate input data, and (iii) that there is a need to integrate MRP with a detailed shop floor control system, such as JIT. See the JIT and Push and Pull entries given in the article **Lot-Sizing**.

Some of the specific limitations of MRP are given below:

1. MRP software assumes that lead times are certain or fixed. It is well known that for most manufacturing environments lead times are uncertain for internal and external reasons. There are also many sources of manufacturing lead time. Some of the more common sources of manufacturing lead time are: queue time, setup time, run time, wait time, and move time.
2. MRP software assumes that all products are produced on a predetermined BOM structure. In some manufacturing, the most efficient production sequence may not be consistent with the bottom-up BOM structure.
3. In many cases it is difficult to make engineering and part changes within the software.

4. MRP software schedules the shop floor on the basis of the BOM, ignoring efficient shop floor control issues.
5. MRP software assumes infinite shop floor capacity.
6. If the MRP software does not consider capacity constraints, the master scheduler must balance capacity by hand each time a change is made to the master schedule. In addition, the complexities of resolving capacity constraints become more complex as the number of master schedulers increase.
7. MRP software does not consider "floating bottlenecks." Depending on changes to the master production schedule, bottlenecks are intractable.

As can be seen from this discussion, MRP is not a stand-alone system. MRP must be integrated with top management and shop floor control if it is to be an effective manufacturing tool.

CONCLUSION

MRP is concerned with the overall logistics of the flow of materials in order to satisfy demand schedules for finished products.

The MRP system coordinates all of the information on the state and activities of the purchasing, production control, and inventory control areas, in order to determine the target, quantity, and time when all materials flow in each of these areas.

MATHEMATICAL MODELS FOR PERISHABLE INVENTORY CONTROL

STEVEN NAHMIA
Operations and MIS Department,
Santa Clara University, Santa
Clara, California

INTRODUCTION

There are thousands of papers describing mathematical models of inventory systems, but a relatively small number consider items which have limited life. However, such items play an important part in everyday life. Virtually all foodstuffs as well as most pharmaceuticals have a limited lifetime. Initial interest in these models was sparked by bloodbanking applications, but the scope of applications is far greater.¹

It is important to understand the different kinds of perishability that have been studied. Fixed life perishability means that the useful lifetime of the item is known in advance to be a fixed number of periods, say m . Exponential decay means that a fixed fraction of the inventory is lost each period. Exponential decay has also been referred to as *age independent perishability*. From the author's experience, few real problems are accurately described by exponential decay, while fixed life perishability has wide-ranging applications. For that reason, we will restrict our attention to fixed life perishability in this article.

One way of classifying inventory models is by the review period. Periodic review means that inventory levels are reviewed at predetermined discrete points in time. Continuous review means that the inventory level is known at all times. Most of the

literature on ordering policies for perishables assumes periodic review. We will also briefly review the major developments under continuous review, although this problem is largely unsolved.

We assume the following definition. A perishable item is one that has constant utility up until an expiration date (which may be known or uncertain), at which point the utility drops to zero. In general, new orders are assumed to be of fresh goods only. What makes perishable inventory problems so difficult to analyze is the fact that on-hand inventory must be age differentiated. In classical inventory analysis, the state of the system is simply the amount of inventory on hand. In that setting, items are indistinguishable. However, in the perishable inventory case, one must distinguish between items of different ages. As items age, their value to the system decreases, since there is the likelihood that they will outdate before being able to satisfy the increase in demand. This results in a multidimensional state space, which severely complicates the analysis.

Another key distinction in inventory models is between deterministic versus stochastic (random) demand. While there are some interesting deterministic problems, the most interesting and challenging problems arise under stochastic demand. For that reason we will focus on that case in this article.

The purpose of this article is to provide the reader with an overview of the basic theory and methods for modeling perishable inventory problems subject to periodic review and uncertain demand at a single installation. Hopefully, the reader will come away with an appreciation of the basic tools required for the analysis, and the important issues in the field. This introduction is not intended to be an up-to-date review of the literature.

THE STATE SPACE

Assume that all orders are for fresh items. If an item is not consumed by demand during a

¹Please note that Opher Baron's piece appearing in this volume also discusses control of perishables. His article is more expository in nature and focuses more on continuous review than periodic review.

period, it remains in inventory, but ages by one period. It is obvious, in this context, that the most cost efficient issuing policy is FIFO (i.e., oldest first). This assumes that the issuing policy is under the control of the producer, not the consumer. When consumers have the opportunity to choose the issuing policy, they will typically choose LIFO (i.e., newest first). For example, in a grocery store, if all of the milk is put on display, consumers will compare expiration dates, and pick the newest cartons. On the other hand, the person stocking the shelves would display only the oldest items, thereby forcing consumers to accept the oldest stock. Very little work has been done on the LIFO issuing policy, so we will assume FIFO unless otherwise stated.

The state space is described in the figure below.

The number in each bin represents the remaining lifetime in periods of the stock in that bin. At the end of each period, remaining stock in each bin is moved to the bin below, and any remaining stock in the last bin must be discarded as outdates.²

Hence it follows that we can represent the state of the system at the start of a planning period before any new orders are placed as $(x_{m-1}, x_{m-2}, \dots, x_1)$, where the subscript

²An outdate is an item that can no longer be used to satisfy demand, either because it is at or past its expiration date, or because its utility has dropped below an acceptable level. An example of the second case is spoiled produce.

is the remaining useful life of the product. We will use y to represent new stock rather than x_m to distinguish between the state variable and the decision variable. Note that we assume zero order lead time and the following sequence of events: at the start of each period, one observes the state vector of on-hand inventories of each age level. One then orders y units of fresh stock which are delivered immediately. Subsequently, the demand in the period is realized. If demand is less than the total stock on hand, it is satisfied by issuing the on-hand stock in FIFO order. If demand exceeds the total stock on hand, the excess demand is either backordered or lost.

Two different approaches to costing have been suggested. One method is to use conventional costing, so that in the current period one pays for ordering, holding and stockouts, and the outdating that occurs in the current period. The outdating in the current period, which is $E[\max(x_1 - D, 0)]$, is independent of the current decision variable, y . Hence, using conventional costing, the effect of outdating will not be seen for m periods, when the current order is exposed to outdating. This was the approach taken by Fries [1].

Nahmias [2] adopted a different approach. His approach was based on computing the expected amount of outdating of the current order, y , m periods into the future, and placing that expectation into the one period cost function. In this way, one can construct a meaningful one period model that includes outdating, and hence incorporate the perishability aspects of the problem into the current decision without requiring m periods of a dynamic programming iteration. As we will see, a side benefit of this approach is that it leads to effective approximations. The downside of this approach is that it significantly complicates the analysis.

DETERMINING OPTIMAL POLICIES

Define the following sequence of random variables:

$$R_1 = y + \sum_{i=1}^{m-1} x_i,$$

$$R_2 = \left[y + \sum_{i=2}^{m-1} x_i - (D_1 - x_1)^+ \right]^+,$$

$$R_3 = \left[y + \sum_{i=3}^{m-1} x_i - (D_2 + (D_1 - x_1)^+ - x_2)^+ \right]^+,$$

and so on.

Then R_i represents the amount of the current on-hand inventory i periods into the future, assuming that we start with $\mathbf{x}$ and order y . Each value of R_i is a random variable, since it is a function of the future demands. Note that the use of the imbedded $+$ functions are necessary to keep track of units lost due to outdating.

To simplify the notation, define the following sequence of random variables recursively:

$$B_0 = 0$$

$$B_1 = (D_1 - x_1)^+$$

$$\vdots$$

$$B_j = (D_j + B_{j-1} - x_j)^+, \text{ for } 1 \leq j \leq m-1.$$

Interpret the random variable B_j as the total unsatisfied demand in period j after depleting the on-hand inventory that would have outdated in period j . It follows that

$$R_m = [y - (D_m + B_{m-1})]^+$$

represents the amount of the current order y that outdates in m periods.

The goal of the analysis is to compute the expected value of R_m and incorporate this into the one period model.

Define $G_n(t; \mathbf{w}_{n-1}) = P(D_n + B_{n-1} \leq t)$, where $\mathbf{w}_i = (x_i, x_{i-1}, \dots, x_1)$. Note that $\mathbf{w}_{m-1} = \mathbf{x}$. One may interpret the random variable $D_n + B_{n-1}$ as the total demand faced by the fresh stock arriving in period n , and $G_n(t; \mathbf{w}_{n-1})$ as the CDF of this random variable.

The following results establish the form of the outdating cost function.

Theorem 1. $G_n(t; \mathbf{w}_{n-1}) = \int_0^t G_{n-1}(v + x_{n-1}; \mathbf{w}_{n-2}) f(t - v) dv$.

Theorem 2. $E(R_m) = \int_0^y G_m(t; \mathbf{x}) dt$.

The term $E(R_m)$ represents the expected amount of the current order, y , which will outdate m periods into the future. By deriving an explicit penalty for outdating of the current order, one can define a one period expected cost function that balances all the relevant costs in the problem, thus avoiding the need to iterate through m periods of a dynamic programming recursion to see these effects.

Whether one uses current costs only or incorporates future outdate costs, the dynamic programming recursion has the form

$$C_n(\mathbf{x}) = \min_{y \geq 0} \left\{ L(\mathbf{x}, y) + \alpha \int_0^\infty C_{n-1}(\mathbf{s}(y, \mathbf{x}, t)) f(t) dt \right\}.$$

The transfer function $\mathbf{s}(y, \mathbf{x}, t)$ has the following form:

$$s_i(y, \mathbf{x}, t) = \left[x_{i+1} - \left(t - \sum_{j=1}^i x_j \right)^+ \right]^+,$$

for $1 \leq i \leq m-2$

and

$$s_{m-1}(y, \mathbf{x}, t) = \begin{cases} y - (t - x)^+, & \text{if excess demand is backordered,} \\ [y - (t - x)^+]^+, & \text{if excess demand is lost,} \end{cases}$$

where $x = \sum_{i=1}^{m-1} x_i$.

The one period expected cost function, $L(\mathbf{x}, y)$, may or may not include the term $E(R_m)$ depending on whether one uses Nahmias' or Fries' formulation. The object of the analysis is to show that the term in brackets is convex in the decision variable, y . The proof requires a multistep induction argument. In addition, one can show that the optimal ordering policy function when i periods remain in the planning horizon, say $y_i(\mathbf{x})$, possesses the following important property:

$$-1 \leq y_n^{(1)}(\mathbf{x}) \leq y_n^{(2)}(\mathbf{x}) \leq \dots \leq y_n^{(m-1)}(\mathbf{x}) < 0.$$

Interpret $y_n^{(i)}(\mathbf{x})$ as the partial derivative of y_n with respect to the i th component of the state vector, $\mathbf{x}$. This means that the order cost function is a decreasing function of each component of the state variable, and furthermore, it decreases more quickly in newer stock than older stock. That is, newer stock has more value to the system.

Dynamic programming is not a practical solution technique for lifetimes of more than two or three periods. As the dimension of the state variable grows, the calculations required grows geometrically (this is known as *Bellman's "curse of dimensionality"*). Hence, approximations are of particular interest.

MYOPIC APPROXIMATIONS

In order to eliminate the curse of dimensionality, it is desirable to find approximations that depend only on the total inventory on hand $x = \sum_{i=1}^{m-1} x_i$. There are several approaches to finding simple approximations. In a simulation study, Nahmias [3] compared several different forms of approximations and determined that the standard S type policy (also known as a *critical number policy*, or an *order-up-to policy*) performed well. Since it is known that the S type policy is optimal for the nonperishable problem, this would seem to be a natural choice.

Given that one has identified the form of the approximate policy, the next step would be to identify the best approximate policy from that class of policies. Finding optimal S type policies was explored by Van Zyl [4] for the case of $m = 2$, and Cohen [5] for the case of $m > 2$. Van Zyl was able to obtain a simple expression for the stationary distribution of the system state, but Cohen could not. However, the case $m = 2$ can easily be solved for an optimal solution, as the dynamic program only has a single dimensional state variable, so Van Zyl's results are of little practical value. And since Cohen could not obtain an explicit expression for the stationary distribution of the state vector, it would appear that this approach leads to pretty much a dead end.

Optimal S policies could conceivably be found by computer simulation. However,

simulations can also be quite tedious for larger values of m . Hence, approximate, and easily computed S policies are of interest. The first to explore this possibility was Nahmias [6]. His approach was somewhat unconventional. He developed approximations of the one period outdating function, $G_m(t; \mathbf{x})$, and the one period transfer function, $s(y, \mathbf{x}, t)$, that were functions of the sum x . Using these approximations, the original problem was transformed into one in which S policies were optimal. Computational tests indicated that the method resulted in effective approximations.

Chazan and Gal [7] developed a different approach to finding an approximate policy. Their method was based on the observation that if demand is bounded by S/m , then it is easy to compute the expected outdating each period under FIFO issuing. In fact, it will be simply $S/m - \mu$. Since the outdating will decrease if demand is larger, this provides an upper bound on the expected outdating each period. They also obtain a lower bound as $S/m - E(\overline{D_T})$, where $E(\overline{D_T})$ is the average demand over m periods truncated S/m .

Although Chazan and Gal do not consider the problem of optimizing the value of S , it turns out that their bounds can be applied to same methods used by Nahmias [6] to construct an approximation. Subsequent tests showed that the Chazan and Gal bounds provided a more accurate approximation than did the Nahmias bounds, and further, their approximation seemed to improve as m increased, while Nahmias' got worse as m increased. By combining the methodology of Nahmias [6] with the bounds of Chazan and Gal [7], one obtains a very efficient and easy way to compute S type approximation for ordering perishable inventory.

The bounds obtained by Chazan and Gal can be expressed respectively as $S/m - a(S)$ and $S/m - b(S)$ where

$$a(S) = \int_0^{S/m} mx f^{m*}(mx) dx + (z/k)(1 - F^{m*}(S))$$

$$b(S) = \int_0^{S/m} xf(x) dx + (S/m)(1 - F(S/m)).$$

Since we have no reason to believe that either the lower or upper bound is more

accurate, a reasonable approximation for the expected outdating based on these bounds is simply the average of the upper and lower bounds. That means we would approximate the outdating function as

$$O(z) = z/m - 0.5(a(z) + b(z)).$$

Using this bound, one can show that an approximate myopic policy is the minimizing value of $W(z)$, given by

$$W(z) = c(1 - \alpha) + L(z) + (\alpha^{m-1}\theta + \alpha c)O(z),$$

where c is the marginal order cost and $L(z)$ is the expected one period holding and penalty cost function. The minimizing value of $W(z)$ is easy to find. The approximation is to order up to the value of z^* that minimizes $W(z)$. This approach should provide very accurate S policy approximations for ordering perishables. (Details of the theoretical basis for this approximation will be presented in more detail in an upcoming monograph by this author.)

FIXED ORDER QUANTITY APPROXIMATION

Consider a system where a fixed quantity of fresh product is added to the inventory each period. This approach was suggested by Brodheim *et al.* [8] to model the operation of a blood bank. In the context of blood banking, a fixed replenishment policy assumption might be reasonable if the bank has a relatively constant pool of donors. However, fixed order quantity policies are likely to be inferior to S policies in terms of cost performance, since they do not respond to demand. Since an S policy orders exactly the previous period's demand, it is responsive to highs and lows in the pattern of demand realizations.

However, the analysis is significantly simplified under a fixed order quantity policy. Suppose q units are brought into the system each period. Then the age distribution of on-hand inventory will be of the form $(q, q, q, \dots, r, 0, 0, \dots, 0)$ where $0 \leq r \leq q$. Notice that this means that knowing only the total stock on hand uniquely defines

the state vector. If the product lifetime is m periods, and the total inventory on hand starting any period is i , then every age category will contain exactly q units up until age category $[i/m]$, which will contain exactly $r = i - [i/m]q$ units. Interpret $[x]$ as the largest integer less than or equal to x .

This means that knowing only the total inventory on hand provides a complete description of the system state, and the total starting stock forms a Markov chain of one dimension. This obviates the need to keep track of the age distribution of stock, and significantly simplifies the analysis. The range of possible values of state is 0 to qm . Since under reasonable assumptions, the resulting Markov chain is recurrent, there exists a stationary distribution $\pi = (\pi_1, \pi_2, \dots, \pi_{qm})$ satisfying $\pi P = \pi$, where P is the one step transition matrix for the chain.

Even though the state is only one dimensional, the number of states is likely to be large for most applications. In the blood banking application, $m = 21$, and for a value of q of 100 the resulting chain has 2100 states. This is certainly not beyond current computing power, but would be, at best, unwieldy. For that reason, approximations are considered, which provide reasonably tight bounds on the probability of shortage and the expected daily outdating. The authors do not consider the problem of optimizing the value of q . While potentially useful in the right environment, this approach is of limited interest (as noted above) due to the fact that a fixed order quantity policy does not respond to demand fluctuations. In the blood banking context, a sudden surge in demand brought on by a catastrophe would certainly be a cause to seek larger supplies of fresh blood.

RANDOM LIFETIMES

An important extension of the basic model is to the case of uncertainty in the product lifetime, which could be an accurate description of obsolescence.³ Such a model

³Obsolescence means that the environment changes and the item is no longer of use. It differs

might also be a more accurate descriptor of fresh food than assuming fixed life. An issue that arises when dealing with lifetime uncertainty is that of crossovers. That is, is it more accurate to assume that items outdate in the same order that they enter inventory or not?

This is precisely the same issue that arises in the standard dynamic inventory model with lead time uncertainty. That is, if orders are placed periods i and j , where $i < j$, should one assume that the order placed in period i arrives prior to that of the order placed in period j ? If so, successive lead times must be dependent random variables. This presents a challenge for modeling, as one rarely finds stochastic models incorporating dependency. This problem was solved very elegantly by Kaplan [9]. Kaplan's approach was adapted by Nahmias [10] to the perishable inventory problem.

The idea is to define a set of surrogate random variables that are independent, and build the distribution of order arrival from the surrogate variables. Let $A_1, A_2, \dots$ be a sequence of independent and identically distributed random variables defined on the discrete set $\{1, 2, \dots, m\}$, where m is interpreted as the maximum lifetime. Note that these surrogate random variables are not successive lifetimes of orders. The assumption is that if the event $(A_n = k)$ is realized in any period, then one assumes that all of the on-hand stock k periods or older outdates in the current period. If no stock is on hand of age k after satisfying demand, no outdating occurs.

This framework can be incorporated into both the analysis of optimal policies and approximate policies. Computation of an optimal policy still requires solution of an $m - 1$ dimensional dynamic program, so again approximations are of critical importance.

We will not go into the details here, but one can show that the expected outdating of the current order y can be expressed as

$$\sum_{k=1}^m r_k \sum_{j_1=2}^m \dots \sum_{j_{k-1}=k}^m \prod_{i=1}^{k-1} P_{j_i} \times \int_{v_k}^{y+v_k} G_k(u, v(k-1)) du,$$

where $P_i = P\{A_n = i\}$, $r_k = \sum_{i=1}^k P_i$, and G_k is the expected outdating function. While this looks very daunting, it can be simplified significantly. We will not present details here, but if one defines

$$q_k = \sum_{k=1}^m r_k \sum_{j_1=2}^m \dots \sum_{j_{k-1}=k}^m \prod_{i=1}^{k-1} P_{j_i},$$

then one can show that $q_k = r_k \prod_{i=1}^{k-1} (1 - r_i)$.

Again, one may adopt the Nahmias' [6] approach to the Chazan and Gal [7] bounds to obtain a myopic one period cost of function of the form

$$W(z) = c(1 - \alpha)z + L(z) + \sum_{k=1}^m q_k (\alpha^{k-1}\theta + \alpha c) \mu_k(z).$$

Since $W(z)$ is quasi-convex, the minimizing value occurs where the first derivative is zero. This results in z^* satisfying

$$c(1 - \alpha) + L'(z) + \sum_{k=1}^m q_k (\alpha^{k-1}\theta + \alpha c) \left\{ \frac{F(z/k) + F^{k*}(z)}{2k} \right\} = 0.$$

One then orders up to z^* each period. Comparisons of this approximation with the optimal policy for lifetimes of 2 and 3 periods, and for a variety of cost and demand parameters, shows close agreement between optimal and approximate policies. One would hope that this would signal that these approximations would also be accurate for longer lifetimes, although such tests have not been done.

INCLUSION OF A SET-UP COST

All of the work reviewed thus far on the periodic review perishable inventory problem

from perishability in that one cannot predict in advance exactly when an item will become obsolete in most applications.

assumes that there is no fixed cost (set-up cost) for placing an order. Fixed order costs can rarely be ignored in practice. In rare occasions, when deliveries are prescheduled on a daily or weekly basis, fixed order costs are sunk costs. However, it is more common that fixed costs determine the optimal frequency of orders, and cannot be ignored.

The results of this section are based on Nahmias [11]. Both optimal and approximate ordering policies are considered. The optimal policy is derived only for the one period problem,⁴ but it is likely the multiperiod version possesses the same policy structure. The optimal policy requires calculation of two functions of the starting state, $s(\mathbf{x})$ and $y(\mathbf{x})$, with $s(\mathbf{x}) \leq y(\mathbf{x})$. These functions determine the optimal policy as follows: if $s(\mathbf{x}) > 0$, the optimal policy is to place an order for $y(\mathbf{x})$, and if $s(\mathbf{x}) \leq 0$, then no order should be placed. As in the case of no setup cost, $y(\mathbf{x})$ minimizes the expected one period cost function, $B(\mathbf{x}, y)$. (That is, $B(x, y(\mathbf{x})) = \min_{y \geq 0} B(\mathbf{x}, y)$.) The function $s(\mathbf{x})$ solves $B(\mathbf{x}, s(\mathbf{x})) = B(\mathbf{x}, y(\mathbf{x})) + K$, and $s(\mathbf{x}) \leq y(\mathbf{x})$, where K is the fixed set-up cost. Since $B(\mathbf{x}, y)$ is convex in y , these equations uniquely define $s(\mathbf{x})$. Note that Nahmias only derived first period results, but given the fact that the structure of the optimal policy is the same for the first period problem as the multiperiod problem when there is no setup cost present, it is reasonable to speculate that this is the case here as well.

Except for product lifetimes of two or three periods, the optimal policy is too complex to be practical. Hence, approximations are of particular interest. The natural form of an approximate policy is (s, S) , since this policy is known to be optimal for the nonperishable problem, and is easy to implement in practice. (An (s, S) policy is one in which an order is placed up to S if and only if the starting inventory position is less than s .) The approach to constructing an approximation follows closely the method discussed above for the case of $K = 0$. That is, the expected outdate function is approximated by a function of the total on-hand inventory

using either the Nahmias or Chazan and Gal bounds, and this approximation is then used to construct a surrogate problem whose optimal solution is used to approximate the original problem. The surrogate problem has only a single dimensional state variable, and is solved by dynamic programming.

Extensive computations reported in Nahmias [11] indicate that the approximation generally gives costs within 1% of the optimal, although because of the difficulty of computing an optimal policy, the comparisons were done for $m = 2$ only. However, the results would seem to indicate that this is a reasonable approach for approximating dynamic perishable inventory problem with a fixed order cost.⁵

MULTIPRODUCT MODELS OF PERISHABLES

Several applications in blood banking give rise to several multiproduct perishable inventory models. The earliest of which we are aware is that developed by Nahmias and Pierskalla [12]. The model was motivated by the operation of a blood bank that stores both fresh and frozen blood. Since frozen red blood cells have a much longer lifetime than fresh blood, the authors assumed that one product had a finite lifetime and the other an infinite lifetime. The model allows for one way substitution, that is, the infinite life time product can be substituted for the finite lifetime product (but not vice versa).⁶

The model developed is a direct extension of the approach applied by Nahmias [2]. Assume that at the beginning of each planning period prior to the realization of demand, orders for both product 1 (the perishable product) and product 2 (the nonperishable product) must be placed. There is a single demand source that depletes first

⁴That is, one planning period. The product lifetime is still assumed to be m periods.

⁵Note that in some cases, such as supermarkets, fixed costs may be unimportant as many items may be ordered simultaneously. However, there still remain many applications in which fixed costs cannot be ignored.

⁶The interested reader should refer to the Rodney Parker piece in this volume for a discussion of multiproduct inventory control for durable goods.

from product 1 according to FIFO, and then product 2 until the demand is either satisfied or backordered. (Note: in the context of blood banking, it is probably more accurate to assume that excess demand is lost rather than backordered. This would mean that excess demand is made up by emergency shipments from other blood banks. The backorder assumption is not crucial to the analysis.)

Costs are charged separately for holding at h_1 for product 1 and h_2 for product 2. Outdating of product 1 is charged at θ and there is a penalty cost of p for unsatisfied demand. Let $\mathbf{x}$ be the vector of on-hand inventories of the perishable product, $x = \sum_{i=1}^{m-1} x_i$, and y the size of the order of fresh stock. In addition, define x^2 as the on-hand inventory of product 2 at the start of any period, and let z be the on-hand inventory of product 2 after ordering in any period, so that the order quantity of product 2 is $z - x^2$. Then the one period expected cost function has the form:

$$\begin{aligned} L(\mathbf{x}, y, z) = & c_1 y + h_1 \int_0^{x+y} (x+y-t)f(t) dt \\ & + \theta \int_0^y G_m(u; \mathbf{x}) du + c_2(z - x^2) \\ & + h_2 z F(x+y) \\ & + h_2 \int_{x+y}^{x+y+z} (x+y+z-t)f(t) dt \\ & + p \int_{x+y+z}^{\infty} (t - x - y - z)f(t) dt. \end{aligned}$$

Assume the following relationships among the cost parameters:

- (i) $0 \leq h_2 \leq h_1$,
- (ii) $0 < c_1 < c_2$,
- (iii) $p > (1 - \alpha)c_2$,
- (iv) $0 \leq (1 - \alpha)(c_2 - c_1) + (h_2 - h_1) < \theta$.

The rationale for these assumptions is the following. Assumption (i) says that the cost of storing the nonperishable product is at least as large as the cost of storing the perishable product. Assumption (ii) says that the cost of acquiring the nonperishable product exceeds the cost of acquiring the perishable product.

Assumption (iii) is common for single product inventory systems. It says that the unit cost of excess demand exceeds the one period discounted cost of acquiring a new nonperishable product. This guarantees that it is not more economical to incur stockouts than purchase new stock—otherwise there would be no motivation to operate the system. The expression in the final case corresponds to the cost of acquiring one unit of product 2 and salvaging it one period later minus the cost of acquiring one unit of product 1 and salvaging it one period later plus the difference in the holding costs. If this term were negative, one would never order product 1. If this term exceeded the outdate cost, it would never be optimal to order product 2.

The analysis proceeds by defining the functional equations based on the expanded state variable $(\mathbf{x}, x^2)$. The authors proceed to show that the optimal policy for the case $m = 2$ can be described by regions in the (x, x^2) plane. Because of perishability, the optimal policy has the unusual property that when one is in an ordering region, the optimal policy calls for ordering an amount that does not take one to the boundary of the ordering region, but to a point in the interior of the region.

In his review, Nahmias [13], showed how the approximation techniques discussed in the previous section could be adapted to this problem. This approximation was never tested, but is likely to be accurate, based on results for the single product problem.

Another multiproduct perishable inventory model, which was suggested by blood banking applications, was explored by Deuermeyer [14]. Consider two production processes, A and B. Process A produces two products (1 and 2), while Process B produces only product 2. Both products are perishable, and both face independent stochastic demands. In the blood banking application, product 1 is platelets (a blood component) and product 2 is whole blood. Process A separates some of the whole blood into platelets and packed red cells, while Process B just produces whole blood.

Suppose that the lifetime of product 1 is m periods and the lifetime of product 2 is l periods. The state vector consists of the

starting stocks of each product at each age level, represented as $(\mathbf{x}, \mathbf{w})$ having dimension $(m - 1) + (l - 1)$. The decision variable is the pair (a, b) , which corresponds to the production quantities for Process A and Process B respectively. Assume that a units of Type A production yields $\eta_1 a$ of product 1 and $\eta_2 a$ of product 2, while b units of Type B production yield b units of Product 2.

Deuermeyer develops a one period model using the expected future outdating of both products in the one period cost function as we did in the section titled “Determining Optimal Policies.” This makes it likely that the structure of the optimal one period policy is the same as the structure of the optimal multiperiod policy. (Unfortunately, due to the complexity of the problem, it was possible to obtain first period results only.)

AGE DIFFERENTIATED DEMAND STREAMS

In a recent study, Deniz *et al.* [15] treat the case where customers demand items of different ages. This situation arises, for example, in the blood banking context where newer blood is required for certain critical surgeries. The authors consider only the case of $m = 2$, so that the age differentiated demand is for either fresh stock or one period old stock. They note that this framework includes both LIFO and FIFO issuing policies.

This study does not treat optimal policies, but considers two heuristic policies. They are labeled TIS and NIS. The TIS policy is what we previously referred to as an *order-up-to-policy* or an *S policy*. The NIS policy is what we previously referred to as *fixed order quantity policy*: one orders S units of new stock independent of the inventory position.

A unique aspect of this study is the assumptions made regarding upward and downward substitution. First, suppose there are given fractions of customers denoted by $0 \leq \pi_D \leq 1$ and $0 \leq \pi_U \leq 1$ who are willing to accept downward and upward substitution respectively. Downward substitution means that a new product is sold to a customer who requests old stock, and upward substitution is the opposite. The authors examine the following four scenarios: no substitution, downward substitution only, upward

substitution only, and both downward and upward substitution. What makes this study interesting and unique is the consideration of four distinct issuing policies. The vast majority of the perishable inventory literature assumes FIFO issuing; and a few studies assume LIFO issuing. The primary focus of this research is to determine under what conditions one of these four issuing rules is preferred given the replenishment policy. In particular, they delineate 10 scenarios involving relationships among the costs and substitution parameters resulting in a preferred issuing policy. We refer the interested reader to their work for further details.

LIFO INVENTORY SYSTEMS

Most of the mathematical models for ordering perishable inventory assume that demands are filled according to FIFO. That is, one depletes the oldest inventory first. From the point of view of the manufacturer, FIFO is the most efficient issuing policy. However, in many circumstances, the decision is not up to the manufacturer, but up to the consumer. One example of this is age differentiated demand streams discussed in the previous section. Other examples are products such as fresh milk that are stamped with an expiration date. Consumers seek the product with the latest expiration date. In some circumstances, paperback books, music CDs, and film DVDs follow LIFO issuing.⁷ Customers are generally much more interested in newer rather than older products. This is typically the case for a video rental service, such as Netflix. Customers queue up for new films, while tens of thousands of older films are rarely requested.

To our knowledge, the only analysis of ordering policies in the context of LIFO issuing is due to Cohen and Pekelman [16]. Using the notation developed earlier, the state of the system after placing an order can be

⁷These are examples of products that are subject to obsolescence rather than perishability. However, the effect is the same: at some point these items are no longer demanded by the consumer.

represented as $(y, x_{m-1}, x_{m-2}, \dots, x_1)$. Under LIFO issuing, the one period transfer function is given by

$$s_i(y, \mathbf{x}, t) = \left[x_{i+1} - (t - y - \sum_{j=i+2}^{m-1} x_j)^+ \right]^+,$$

for $1 \leq i \leq m-2$

and $s_{m-1}(y, \mathbf{x}, t) = (y - t)^+$ under lost sales.

(Note: $s_{m-1}(y, \mathbf{x}, t) = y + \sum_{j=1}^{m-1} x_j - t$, if $t > y + \sum_{j=1}^{m-1} x_j$ under backordering. However Cohen and Pekelman only considered the lost sales case.)

The analysis in Cohen and Pekelman does not proceed along the lines of prior work. That is, they do not develop the dynamic programming functional equations in order to analyze the properties of an optimal ordering policy. Rather, they assume fixed amounts of fresh stock that enter the system, and proceed to analyze the underlying stochastic processes arising from the age distribution process. In fact, to our knowledge, no one has attempted to discover the properties of an optimal policy under LIFO issuing.

The authors develop an analysis of the demand flow process and show how this relates to a ladder height process, which can be posed as a Weiner–Hopf integral equation. However, they obtain a solution to this equation only for the case $m = \infty$ and exponentially distributed demand, which does not shed much light on the perishable case or the general demand case. For $m < \infty$, explicit results are obtained for the case $m = 1$ only and shortage and outdate bounds are obtained for the more general case. It is unclear what the value of these bounds would be for constructing order policies.

Obviously, the LIFO problem has difficulties that the FIFO problem does not. Perhaps, this is why the problem has remained largely unsolved, and is an area of research opportunity.

INVENTORY DEPLETION MANAGEMENT

The inventory depletion management problem is the following. Items are stored in a stockpile for the purpose of serving a demand

in the field. Items typically age at different rates in the stockpile and in the field. The stockpile may or may not be replenished, and there may be different costs to replenish the stockpile and make emergency replacements in the field. The vast majority of the analysis on this problem is to determine conditions under which either FIFO (i.e., issuing the oldest item next) or LIFO (issuing the newest item next) is optimal.

How does this problem relate to the problem of ordering perishable inventory? The problems are similar in that they both deal with optimal management of perishable inventory. But that is where the similarity ends. In the basic perishable inventory problem, items are assumed to be of uniform utility to the field irregardless of their ages at issue, as long as they have not expired in inventory. This means that from the inventory management point of view, it is optimal to issue the items in FIFO order. The classic inventory depletion problem is static in most cases: most of the research assumes a fixed stockpile of items with no opportunity for replenishment. There is also no external demand, other than the “field.” Items are simply issued on a one-at-a-time basis as they die in the field. For the ordering problem, once items are “issued” (i.e., leave inventory to satisfy demand) they leave the system. One is not concerned with how long these items last in the field. In the inventory depletion management problem, the key driver is the relative rates of aging in the stockpile and in the field.

Hence there is little crossover between the inventory depletion problem, and that of ordering perishable inventory. It is clear that there is a large body of real problems in which one must determine replenishment policies for perishables. On the other hand, the inventory depletion problem is more specialized, and would appear to have fewer applications in the real-world.

Irregardless, there is a fairly large body of research on the depletion problem, which is why we review it in detail here. The first study of the depletion problem was put forth by Greenwood [17]. Greenwood’s interest in the problem clearly arose from military applications. As he notes in his introduction, the

prevailing thinking of the time was that FIFO was the preferred issuing order, but that LIFO might be a better choice in many cases. Greenwood notes that the basic trade-off is that under FIFO, issuing will be occurring frequently, but fewer items will expire in the stockpile; while under LIFO, one will observe longer field lives, but many items might expire in storage. Greenwood's basic observation is that if the field life function is linearly decreasing with slope one, both LIFO and FIFO are optimal, but if the field life function is convex, LIFO is optimal and if it is concave FIFO is optimal. He notes that when the field life function is convex and decreasing, FIFO requires substantially more replenishment of the stockpile. Formal proofs of these results were not provided.

Later, Derman and Klein [18] consider a rigorous analysis of a more narrowly defined problem. Virtually all of the research that followed is based on Derman and Klein's formulation, which is the following. Assume a fixed stockpile of n items of varying ages, say $(S_1, S_2, \dots, S_n)$. Items are issued one-at-a-time to the field upon expiration of the previously issued item. An item issued at age S has a field life of $L(S)$, where $L(S)$ is a known function (later extensions would consider the case, where field life is a random variable). The objective is to determine the sequence in which to issue the items so as to maximize the total field life (or total expected field life) of the stockpile.

Consider the following example. Many portable electronic items, such as digital cameras, mp3 players, and flashlights use disposable batteries. As batteries fail, they are replaced. Batteries age in storage, but much more slowly than while in use. Given a stockpile of batteries of varying ages, in what order should the batteries be issued to maximize the total useful lifetime of the stockpile?

As noted above, in the case of the standard perishable inventory ordering problem, the issue of field life never arises. Items are assumed to age at unit rate while in storage, but once issued to meet demand, they leave the system. In the basic perishable inventory model, a new item with remaining lifetime m has the same utility to the buyer as an

item with one unit of time remaining in its lifetime. To this writer's knowledge, the only study which considers both ordering and issuing of perishable items is the unpublished work of Veinott [19], but only deterministic demand was considered in this study. Treating both ordering and issuing of perishable inventory under general stochastic demand would be very difficult.

Consider the field life function, which defines the relative rates of aging in the stockpile and in the field. The simplest assumption is that items age at the same rate in the field as in the stockpile. This would correspond to a field life function of the form $L(S) = m - S$, where m is the useful lifetime of a new item. Note that in this case, we would require that $L(S) = 0$ for $S > m$. As we will see, this is a trivial case in which all issuing policies are optimal. However, if items age at different rates in the stockpile and in the field, the field life function will not have unit slope. Suppose, for example, that items in the stockpile are refrigerated and age at exactly half the rate of items in the field. In this case, the appropriate field life function is $L(S) = 0.5(m - S)$, where m should be interpreted as the lifetime of a new item that remains in the stockpile until it expires. We would expect that many real cases can be expressed in the form $L(S) = b(m - S)$, where the slope term b indicates the relative rate of aging of items in the stockpile and the field. In virtually all of the real-world applications, we can envision $0 \leq b \leq 1$, implying that items age more quickly in the field than in the stockpile.

As noted earlier, Derman and Klein defined the problem more narrowly than Greenwood. This allowed them to develop rigorous proofs of their results for more general forms of $L(S)$. Their article was significant in several respects. One was their problem definition. More importantly, they discovered what would become the standard approach for analyzing the issuing problem, namely, an induction argument on n , the number of items in the stockpile. Derman and Klein's main result is: if (i) $L(S)$ is a positive convex function and (ii) LIFO is optimal when $n = 2$, then LIFO is optimal when $n \geq 3$.

Zehna [20] points out that one must qualify the assumptions of this theorem. It is

untrue, for example, if $L(S)$ is an increasing function, or is not monotone. As noted earlier, this is unlikely to occur in the real-world, as it implies that items improve in the field. He also points out that the assumption made by Derman and Klein that issuing a single item is never optimal may, in fact, not be true in all circumstances. Zehna provides a proof of the slightly modified theorem that does not require this assumption. It is:

Theorem 3. *If $L(S)$ is a convex, nonincreasing function and LIFO is optimal for $n = 2$, then LIFO is optimal for all $n \geq 2$.*

For this result to be useful, one still needs to determine those convex functions for which LIFO is optimal when $n = 2$. Two examples presented by Derman and Klein are (i) $L(S) = a/(b + S)$, for $a > 0, b \geq 0$ and (ii) $L(S) = ce^{-ks}$ ($c, k > 0$). (Note that the first case was misprinted in the original as $L(S) = (a/b + S)$.) In both cases, the field life function is monotonically decreasing, so they do correspond to perishable items. Both functions are also nonlinear.

The first extension of the Derman and Klein work was due to Lieberman [21], who showed that if $L'(S) \geq -1$ and LIFO is optimal for $n = 2$, then LIFO is optimal for $n > 2$; and, if FIFO is optimal for $n = 2$, then FIFO is optimal for $n > 2$.

Zehna also provided several extensions of Derman and Klein's and Lieberman's results. He considers cases, where $L'(S) < -1$ and shows that LIFO is optimal in both cases where L is convex or concave. However, this is an unlikely case, as it implies that items age faster in stockpile than in the field. Zehna was also the first to consider stochastic field life functions, but obtained few results for this case.

As noted earlier, Derman and Klein's original work sparked a series of articles. In the opinion of this writer, most of these are of limited practical interest because of Derman and Klein's earlier result that, if the form of the field life function is known, all inventory problems can be solved as assignment problems. One of these minor extensions was due to Bomberger [22], who extended Derman

and Klein's results based on properties of the inverse function $L^{-1}(S)$.

Eilon [23] focused on the problem of whether LIFO or FIFO is optimal for the case $n = 2$. This is of interest since most of the earlier work used the Derman and Klein induction argument, which requires one to assume that LIFO or FIFO is optimal for $n = 2$. One interesting idea was that if one expressed the field life function as a power series expansion, one can find conditions for the optimality of LIFO or FIFO for two items based on these expansions. In a later work, Eilon [24] focused on the problem of providing closed form expressions for the total field life of a stockpile under several circumstances. He considered cases of identical items, and nonidentical items. He also considered the case where items flow into the stockpile at a constant rate. The replenishments could be of identical or nonidentical items.

Pierskalla [25] made several important contributions to the issuing problem. He extended the earlier work to include multiple demands on the stockpile, inclusion of penalty costs for issuing, and S -shaped field life functions. Several researchers considered the extension to the case of random field lives, but these results required strong assumptions. These studies include Pierskalla [26], Nahmias [27], and Albright [28].

CONTINUOUS REVIEW

Continuous review means that the state of the inventory system is known at all times, as opposed to periodic review, where the state of the system is known only at discrete points in time labeled periods. Surprisingly, very little is known about optimal ordering policies for fixed life perishables under continuous review. The difficulty is that when an order lead time is present, aging is applied only to the units on hand, and not to the units on order. Furthermore, since units may be ordered at any point in time, there is no limit to the number of different orders that comprise the on-hand inventory at any point in time. Hence, the vector describing the on-hand inventory of each age level has an unlimited number of dimensions.

One way to circumvent this problem is to assume zero order lead time. It is the belief of the author that the simultaneous assumptions of continuous review and zero order lead time are unrealistic, and it is likely that these models have little practical value. Note that there is a big difference between assuming zero order lead time in periodic review systems and in continuous review systems. In the former case, it only means that the lead time is less than a review period, as orders are assumed to be placed at the beginning of the planning period, and are assumed to arrive at the end of the planning period. In the case of continuous review, it means that orders arrive instantaneously. For that reason, the policies obtained are not likely to be useful in a practical setting. However, they may provide a theoretical stepping stone to the more realistic problem with positive lead times.

The first to explore this approach was Weiss [29]. Weiss assumed that demands are generated by a stationary Poisson process with fixed rate λ . His main result is that, in the case of lost sales, the form of the optimal policy is to either never order, or to order to a fixed level S when the inventory level drops to zero. Notice that the issue of perishability never really comes up, as order cycles are completely independent. One simply waits until the inventory level drops to zero (whether through demand or outdating), and replenishes to a fixed level [much as one does in the simple economic order quantity (EOQ) model].

Weiss' results were generalized by Liu and Lian [30]. They assumed full backordering of demand and generalized from a Poisson demand process to a stationary renewal process. They showed that the form of the optimal policy is (s, S) with $s \leq -1$, and provide explicit formulas for computing the optimal policy parameters. Note that the form of the policy (namely, that one only orders when the system is backordered), depends heavily on the assumption that order lead times are zero. It is unlikely that one would use such a policy in the real-world, where order lead times are always positive. Hence, it would appear that these results do not provide much insight into the general continuous review perishable inventory problem.

It is worth noting that the primary driver of the continuous review heuristic (Q, R) inventory models that form the basis for most commercial inventory control systems is uncertainty of demand over the replenishment lead time. Were lead times reduced to zero, optimal order quantities would collapse to the simple EOQ formula and reorder levels would be zero. (See Nahmias [31], Chapter 5)

When there is a positive lead time for ordering, the form of an optimal order policy for perishables under continuous review is not known. Part of the problem is defining the state of the system. As noted above, the state could be an infinite-dimensional vector of all previous orders placed and their ages. Given the complexity of the continuous review problem, a reasonable starting point is to find the best policy from a prespecified class of policies.

There is a large stream of research that exploits the analogy between queues with impatient customers and the perishable inventory problem. Consider a queueing system in which customers are willing to wait no more than m units of time in the queue for service. If we identify the queue with the on-hand inventory, the arrival process with the replenishment process, and the service process with the demand process, the analogy is clear. However, queueing models tend to be descriptive rather than prescriptive, as are inventory models. It is not clear that they shed much light on optimal ordering policies. It is rare that replenishments occur according to a random process. One real-world situation where this assumption is reasonable is in blood bank management. Blood is replenished via donations that do occur randomly on a one-at-a-time basis. The blood bank might have some control over the rate of replenishment via appeals. Hence, a queueing model in which the customer arrival rate is a control variable could be an accurate description of a blood bank.

Nahmias [32] appears to be the first to consider such a model. He assumes a simple $M/M/1$ queue with fixed customer impatience and considers optimization of the arrival rate to balance shortage and outdating costs. Graves [33] was the first to notice that the virtual waiting time process

could be used to derive the process for the age of the oldest unit in inventory. Although he does not explicitly show how, this approach could be used to optimize the arrival rate under certain conditions.

There is a large stream of research on queueing-based models, such as that carried out by Kaspi and Perry [34] and extensions, which we will not review here. These appear to be essentially descriptive, and have not yet been exploited to obtain optimal order policies.

One for One ($S-1, S$) Policies

The only rigorous analysis of a continuous review perishable inventory system with positive order lead time of which we are aware is Schmidt and Nahmias [35] (and an extension by Perry and Posner [36]). They assumed a so-called $(S-1, S)$ policy in which the inventory position (stock on hand plus stock on order) is maintained at a fixed level S . Assume that demands occur one-at-a-time, which would be the case, for example, if demands were generated by a stationary Poisson process. For nonperishables, an $(S-1, S)$ policy places an order for one unit at each occurrence of a demand. With perishability, orders are placed at both the occurrence of demands and outdating. $(S-1, S)$ policies are optimal for very high value items, and are common in military resupply and repair systems. A common maintenance strategy for high value equipment is to perform maintenance when the equipment fails or at fixed intervals, whichever comes first. Since unplanned failures occur at random, these can be modeled as a stochastic process, and may be labeled the demand process. If an item reaches age m and has not failed (i.e., been demanded), it is taken out of the system for routine maintenance, and thus “outdates.” Hence, the extension of traditional $(S-1, S)$ policies to the case of fixed life perishable inventories can be useful for modeling maintenance systems.

As noted above, what makes the problem difficult is the interaction of perishability and the order lead time. Assume that demands, (i.e., failures), occur one-at-a-time completely at random according to a stationary Poisson process with rate λ . Costs are charged in the

usual way against proportional ordering at c per unit, holding at h per unit held per unit time, outdating at θ per unit, and lost sales at p per unit of unsatisfied demand. Assume a positive order lead time of τ .

The analysis proceeds by analyzing the multidimensional stochastic process $\xi(t) = (\xi_1(t), \xi_2(t), \dots, \xi_S(t))$ defined as the amount of time elapsed since the last S orders were placed. Given the stationary distribution of this process, one can derive the steady-state distribution of the on-hand inventory at a random point in time. From this, one can derive the steady-state distribution of the on-hand inventory at a random point in time, say $(P_0, P_1, \dots, P_S)$, and use that to obtain an explicit expression for the expected cost rate as a function of S .

Perry and Posner [36] developed the following extension of this model. Suppose that customers arriving to the system, when it is out of stock, are willing to wait a random amount of time Y for the next arrival of a unit. The rationale for this extension is that one can keep track of the times of orders, so one can determine the instance of the next arrival. If this is imminent, it makes sense that a customer would wait rather than leave the system unsatisfied. While this extension is interesting, and could be potentially useful in some circumstances, the authors do not provide any calculations to compare the results of their model to those of Schmidt and Nahmias [35]. Until that is done, there is no way to tell if their extension leads to policies that differ significantly from those computed assuming customers do not wait when the system is out of stock.

Optimal (Q, r) Policies with Positive Lead Time

Short of finding optimal policies, a common method in inventory control is to determine the best policy from a class of policies. This is the approach taken by Berk and Gurler [37]. It is well known that for many nonperishable continuous review systems, the optimal policy is a (Q, r) policy. That is, when the inventory position hits r , an order for size Q is placed. Because the form of the optimal policy is not known, it would seem natural to consider the best (Q, r) policy in the perishable inventory setting. In their

analysis, the authors treat separately those cases where there is only single outstanding order permitted, and those where multiple outstanding orders are permitted. They also assume throughout that demands are generated from a stationary Poisson process, thus allowing them to make use of the memoryless property of the exponential interarrival time distribution.

Because items can perish, a slight modification of the standard policy is required. In nonperishable continuous review systems, one is guaranteed that an order can be placed at the instant the inventory level (or inventory position when more than one outstanding order is allowed) hits the reorder point, r . However, if only a single order is in inventory, the entire order will perish at the same instant, thus dropping the inventory level immediately to zero. Hence the policy must be modified to: one orders Q units whenever the inventory level hits r or zero, whichever comes first.

This modification points out the inadequacy of this policy, however. Consider a blood bank storing a rare form of blood (e.g., AB negative). Suppose that the lead time for replenishment is 3 weeks owing to the difficulty of finding donors with this blood type. Also, suppose that there is a substantial amount of AB negative blood on hand due to outdate in 1 day. According to this policy, the blood bank would sit on their current supply until it outdates the next day, dropping their inventory to zero. During the 3-week lead time, there would be no AB negative blood available, precipitating a crisis situation. (Note that this problem does not arise in the model considered by Schmidt and Nahmias [35], since all orders are for size one only, so the on-hand inventory level can only drop by one unit at a time independent of whether the drop is due to outdating or filling demand.)

Clearly, perishability fundamentally changes the form of the optimal policy. The blood bank seeing that their supply of this rare blood type would soon expire would take steps to replenish their inventory well in advance of the outdating. Hence, this type of (Q, r) policy does not make sense in this context. Before one can consider effective heuristics for this problem, a better

understanding of the nature of the optimal policy is required.

Another Potential Approach

In order to make the continuous review problem tractable, it would be valuable if we were able to find a single dimensional surrogate variable that conveys the key information about the on-hand inventory. Note that simply considering the total number of units on-hand irrespective of the age distribution of these units is inadequate, as pointed out in the example above. We propose that one should base a replenishment rule based on the expected remaining lifetime of the on-hand inventory. In the queueing context, this corresponds to the expected time to clear the current queue irrespective of future arrivals. Unfortunately, the calculation of this surrogate measure appears to be quite difficult, but could ultimately lead to an effective control mechanism. (i.e., one would wait until the expected lifetime of the on-hand inventory dropped to a critical level, and then place an order for Q units.)

THE APPLICATION OF PERISHABLE INVENTORY THEORY

This introduction to perishable inventories has focused on the development of the mathematical models that constitute the underlying theory. To what extent have these (or other) mathematical models been used in the real-world? The answer does not appear to be very much.

Throughout this article, it was emphasized that food management is perhaps the most significant potential area of application. Grocery store sales alone account for billions of dollars daily. A modest \$50 weekly grocery bill per person translates into an annual expenditure of \$750 billion in US alone—and this excludes restaurant receipts. Clearly, the potential for savings in food management is enormous. Unfortunately, not a great deal seems to be known about how grocery chains manage their inventories. Efficient inventory management provides a powerful competitive edge in this industry, making the large chains very tight lipped about their procedures.

We also noted that much of the research in perishable inventory theory was motivated by blood bank management. There is substantial literature on the application of analytical methods to blood banking. A good summary can be found in Prastacos [38]. The blood banking problem is much more complex than the relatively simple structures considered here. There are eight major blood types, whose frequencies vary from 38% (O+) to 0.5% (AB-). Blood is collected in units (one pint per donor) at a collection site such as a regional blood center, hospital blood bank, or mobile unit. Blood requests are issued at the hospital blood bank level, where blood is typed, stored, and issued to meet transfusion requests. A unique aspect of blood banking is cross matching. Donor and receiver blood (and possibly organs) must be tested prior to transfusion for compatibility.

This process can take several days. Another important aspect of the problem is the difference between amounts requested and amounts used. Surgeons will typically build in safety stock when they request blood. That is, in order to insure that they do not run out during surgery, they will request more than they expect to use. This feature was not included in any of the mathematical models we reviewed. Hence, a key part of blood bank management is determining the conditional distribution of usage given request size. Several researchers have attacked this problem (refer to the discussion in Prastacos [38] for developments in this area). Hence, a mathematical model of blood banking would have to include these complex features.

Radioactive fuels and pharmaceuticals are two products that exhibit continuous exponential decay. Inventory management of radioactive drugs was considered by Emmons [39] and Nahmias and Levine [40]. Emmons considered the relationship between the nucleotide generator and the products that are derived from that generator (commonly referred to as *parent/daughter relationship*). Although the degree of radioactivity does follow exponential decay, the analysis employed by Emmons did not rely on any of the exponential decay models of inventory management subject to exponential decay that appeared in the literature. Nahmias

and Levine also considered inventory management of radioactive pharmaceuticals, but were interested in the cost/benefit trade-offs of two isotopes of iodine used in the treatment of certain types of tumors. Again, their analysis did not rely upon traditional inventory control models.

MATHEMATICAL PROGRAMMING APPROACHES TO THE TRAVELING SALESMAN PROBLEM

ADAM N. LETCHFORD

ANDREA LODI
DEIS, Università di Bologna,
Bologna, Italy

The *Traveling salesman problem* (TSP) is probably the best known combinatorial optimization problem. Informally speaking, one is given a set of cities, along with the cost of traveling between each pair of cities, and one wishes to find a tour of all the cities of minimum cost. The TSP has applications, not only in OR/MS, but in many other fields. In fact, there are no fewer than four books devoted to it [1–4].

The TSP is notoriously hard to solve, being one of Karp's original $\mathcal{NP}$ -complete problems [5]. Nevertheless, and surprisingly, large-scale instances arising in practice can be often solved to proven optimality (or near-optimality) by sophisticated mathematical programming techniques. This article gives an introduction to these techniques.

The article is structured as follows. We begin by reviewing some of the basic mathematical programming formulations of the TSP. We then discuss polyhedral theory, which is used to derive stronger formulations. Next, we discuss separation routines, which are used to strengthen formulations iteratively. Finally, we discuss exact algorithms for the TSP based on such strengthened formulations.

We remark that some other effective techniques for tackling the TSP exist. For an introduction to *combinatorial* TSP algorithms (i.e., algorithms that work with graph-theoretic relaxations rather than linear programming relaxations), see the article titled **Combinatorial Traveling Salesman Problem Algorithms** in this

encyclopedia. For heuristic and metaheuristic approaches (which give good, but not necessarily optimal solutions), see the article titled **Heuristics for the Traveling Salesman Problem** in this encyclopedia.

Throughout this article, we distinguish between the *symmetric* TSP (STSP), in which the cost of traveling from city A to city B is the same as the cost of traveling in the reverse direction, and the *asymmetric* TSP (ATSP), in which these costs are permitted to be different.

FORMULATIONS

Combinatorial optimization problems can often be formulated in several different ways—see the article titled **Formulating Good MILP Models** in this encyclopedia. In the case of the STSP, the standard formulation is the following, due to Dantzig *et al.* [6]. We are given a complete undirected graph G , with node set V and edge set E . For each $e \in E$, we let c_e denote the cost of traversing edge e . For any node set $S \subset V$, we let $\delta(S)$ denote the set of edges with exactly one end-node in S . Next, for each edge $e \in E$, we define a binary variable x_e , taking the value 1 if and only if edge e is in the tour. Finally, for any set of edges $F \subset E$, we let $x(F)$ denote $\sum_{e \in F} x_e$. The STSP is then equivalent to the following zero–one linear program (0–1 LP):

$$\begin{aligned} \min \quad & \sum_{e \in E} c_e x_e \\ \text{s.t.} \quad & x(\delta(\{i\})) = 2 \quad (\forall i \in V) \end{aligned} \quad (1)$$

$$x(\delta(S)) \geq 2 \quad \left(\forall S \subset V: 2 \leq |S| \leq \frac{|V|}{2} \right) \quad (2)$$

$$x \in \{0, 1\}^{|E|}. \quad (3)$$

The equations (1), called *degree equations*, simply express the fact that the salesman must arrive at and depart from each city. The inequalities (2), called *subtour elimination constraints* (SECs), ensure that the tour is connected.

The ATSP can be formulated in a similar way. Now we have a complete directed graph G , with node set V and arc set A . For each $a \in A$, we let c_a denote the cost of traversing arc a . For any set $S \subset V$, we let $\delta^+(S)$ denote the set of arcs going from S to $V \setminus S$, and $\delta^-(S)$ denote the set of arcs going in the reverse direction. For each arc $a \in A$, we have a binary variable x_a . The ATSP is then equivalent to the following 0–1 LP:

$$\min \sum_{a \in A} c_a x_a$$

$$\text{s.t. } x(\delta^+(\{i\})) = 1 \quad (\forall i \in V) \quad (4)$$

$$x(\delta^-(\{i\})) = 1 \quad (\forall i \in V) \quad (5)$$

$$x(\delta^+(S)) \geq 1 \quad \left(\forall S \subset V: 2 \leq |S| \leq \frac{|V|}{2} \right) \quad (6)$$

$$x \in \{0, 1\}^{|A|}. \quad (7)$$

The equations (4) and (5) are called *out-degree* and *in-degree* equations, respectively. The inequalities (6) are again called *SECs*.

Note that, in both formulations, the SECs are exponential in number. It is in fact possible to formulate the STSP and ATSP as 0–1 LPs in which the number of constraints is polynomial, provided that one is willing to introduce a polynomial number of additional variables. An extensive survey of such alternative formulations was recently given by Öncan *et al.* [7]. Nevertheless, the formulations given here have been found to be very useful in practice, and are therefore the most commonly used. The large number of SECs is not a serious problem, since one can generate the SECs dynamically as cutting planes (see **Branch and Cut**).

POLYHEDRAL THEORY

In this section, we review some of the known polyhedral results for the TSP. We cover the symmetric case first, and then the asymmetric case. We assume that the reader is already familiar with the polyhedral approach to combinatorial optimization problems, which is covered in the article titled **Basic Polyhedral Theory** in this encyclopedia.

The Symmetric Traveling Salesman Polytope

The convex hull in $\mathcal{R}^{|E|}$ of solutions to the system (1)–(3), for a given number n of nodes, is called the *symmetric traveling salesman polytope of order n* , and is denoted by $\text{STSP}(n)$. The first systematic study of $\text{STSP}(n)$ was performed by Grötschel and Padberg [8], who proved the following results:

- The degree equation (1) give a complete and nonredundant description of the affine hull of $\text{STSP}(n)$.
- The nonnegativity inequalities $x_e \geq 0$, for all $e \in E$, define facets of $\text{STSP}(n)$ for $n \geq 4$.
- The SECs (Eq. 2) define facets of $\text{STSP}(n)$ for $n \geq 4$.
- Let H be a subset of V with $3 \leq |H| \leq n - 2$ and let $F \subset \delta(H)$ be a set of node-disjoint edges with $|F| \geq 3$ and odd. The *blossom* inequality $x(\delta(H) \setminus F) \geq x(F) - |F| + 1$ defines a facet of $\text{STSP}(n)$.

Grötschel and Padberg [8] also proved a “lifting” theorem that enables one to convert simple facets into more complex facets. When lifting is applied to the blossom inequalities, one obtains the following *comb* inequalities:

$$x(\delta(H)) + \sum_{j=1}^t x(\delta(T_j)) \geq 3t + 1.$$

Here, $t \geq 3$ is an odd integer, H is a proper subset of V (called the *handle*), and $T_1, \dots, T_t$ are disjoint node-sets (called the *teeth*), such that $T_j \cap H \neq \emptyset$ and $T_j \setminus H \neq \emptyset$ for $j = 1, \dots, t$.

The comb inequalities are undoubtedly a very important class of inequalities for the STSP. They are used in all branch-and-cut algorithms of which we are aware.

Since the publication of Ref. 8, the polytope $\text{STSP}(n)$ has been studied in great depth. Several generalizations of the comb inequalities are known, with exotic names like *clique-tree*, *star*, *hyperstar*, *bipartition*, and *binested* inequalities. There are also several other classes of facet-inducing inequalities known, such as *chain*, *ladder*, *crown*, and *hypohamiltonian* inequalities. For the sake of space, we do not review these developments here, and

refer the reader to the excellent surveys by Grötschel and Padberg [9], Jünger *et al.* [10], and Naddef [11]. We will, however, mention some of the inequalities again, in subsequent sections.

The Asymmetric Traveling Salesman Polytope

The convex hull in $\mathcal{R}^{|A|}$ of solutions to the system (4)–(7), again for a given n , is called the *asymmetric traveling salesman polytope of order n* , and is denoted by $\text{ATSP}(n)$. A survey of early work on $\text{ATSP}(n)$ was given by Grötschel and Padberg [9]. Some of the key early results are as follows:

- The out- and in-degree equations (4)–(5) define the affine hull of $\text{ATSP}(n)$, and all but one of them (arbitrarily chosen) are linearly independent.
- The nonnegativity inequalities $x_a \geq 0$, for all $a \in A$, define facets of $\text{ATSP}(n)$ for $n \geq 4$.
- Any valid inequality for $\text{STSP}(n)$ can be converted into a valid inequality for $\text{ATSP}(n)$, by simply replacing x_e with $x_{ij} + x_{ji}$ for all edges $e = (i, j) \in E$. The resulting inequalities are called *symmetric*.
- The SECs (Eq. 6), which are symmetric, define facets of $\text{ATSP}(n)$ for $n \geq 4$.

Grötschel and Padberg [9] also list various *asymmetric* inequalities. Among them, we mention the so-called D_k^+ and D_k^- inequalities, which have proven to be fairly useful in practice. The D_k^+ inequalities take the form:

$$x_{i_1 i_k} + \sum_{h=2}^k x_{i_h i_{h-1}} + 2 \sum_{h=2}^{k-1} x_{i_1 i_h} + \sum_{h=3}^{k-1} x(\{i_2, \dots, i_{h-1}\}, i_h) \leq k-1, \quad (8)$$

where $(i_1, \dots, i_k)$ is any sequence of $k \in \{3, \dots, n-1\}$ distinct nodes. The D_k^- inequalities are derived from the D_k^+ inequalities by simply swapping the left-hand side coefficients of the two arcs (i, j) and (j, i) , for all $i, j \in V$, $i < j$. This is a perfectly general operation, called *transposition* in Ref. 9.

Another important class of inequalities, which turns out to be very useful in practice, was introduced by Balas [12]. Two distinct arcs (i, j) and (u, v) are called *incompatible* if $i = u$, or $j = v$, or $i = v$ and $j = u$; *compatible* otherwise. A *closed alternating trail* (CAT) is a sequence $T = \{a_1, \dots, a_t\}$ of t distinct arcs such that, for $k = 1, \dots, t$, arc a_k is incompatible with arcs a_{k-1} and a_{k+1} , and compatible with all other arcs in T (with $a_0 := a_t$ and $a_{t+1} := a_1$). Now, call a node v a *source* if $|\delta^+(v) \cap T| = 2$, and a *sink* if $|\delta^-(v) \cap T| = 2$. Note that a node can be a source and a sink simultaneously. Let Q be the set of arcs $(i, j) \in A \setminus T$ such that i is a source and j is a sink. Given a CAT T with t odd, the *odd CAT inequality* $x(T \cup Q) \leq \lfloor t/2 \rfloor$ is valid for $\text{ATSP}(n)$. Balas [12] proved that odd CAT inequalities define facets of $\text{ATSP}(n)$ under mild conditions.

There exist several other articles on $\text{ATSP}(n)$. Again, for the sake of brevity, we do not review them all here, and refer the reader to the excellent survey [13].

SEPARATION ROUTINES

In order to use a class of valid inequalities as cutting planes, one needs a *separation routine*, that is, a routine for detecting when an inequality in that class is violated by a given LP solution x^* (see **Branch and Cut**). As usual, we distinguish between *exact* separation routines, which find a violated inequality in that class whenever one exists, and *heuristic* separation routines, which may fail to find a violated inequality.

Separation Routines for the STSP

Several positive results are known concerning the complexity of exact separation for various inequalities:

- As noted by Hong [14], SEC separation amounts to a minimum weight cut problem, and is therefore solvable in polynomial time. (The current fastest deterministic minimum weight cut algorithm is that of Nagamochi *et al.* [15].)
- The separation problem for the blossom inequalities can be solved in polynomial

time (Padberg and Rao [16]). The current fastest algorithm is that of Letchford *et al.* [17].

- There exists a polynomial-time separation algorithm for a class of inequalities that includes all blossom inequalities and a large subclass of the comb inequalities (Fleischer *et al.* [18]).
- There is a polynomial-time algorithm that generates a violated valid inequality whenever a comb inequality is violated by 1 (Caprara *et al.* [19]).
- There exists a polynomial-time separation algorithm for a class of inequalities that includes all comb inequalities with a fixed handle H (Caprara and Letchford [20]).
- The separation problem for bipartition inequalities (and therefore comb and clique-tree inequalities) can be solved in polynomial time, provided the number of teeth is bounded by a constant (Carr [21]).
- More generally, there exists a polynomial-time separation algorithm for any class of inequalities that can be obtained by “lifting” an inequality that defines a facet of STSP(n), for constant n (Carr [22]).

Further positive results are known for the case in which the *support graph* is planar. (The support graph is the graph induced by the edges with positive x^* -value.) Fleischer and Tardos [23] found an $\mathcal{O}(n^2 \log n)$ algorithm that produces a violated comb inequality whenever a comb inequality is violated by 1, and Letchford [24] gave an $\mathcal{O}(n^3)$ exact separation algorithm for a generalization of the comb inequalities, called *domino-parity* inequalities. Further results for the planar case can be found in Ref. 25.

In addition to these exact separation results, there exists a wide range of separation heuristics. For example:

- Crowder and Padberg [26] presented a fast heuristic for SECs, that is based on the idea of iteratively “shrinking” the support graph by identifying certain pairs of nodes.
- Grötschel and Holland [27] proposed a heuristic for comb separation, in which one first shrinks the support graph, and then calls an exact blossom separation algorithm on the shrunk support graph.
- Padberg and Rinaldi [28] presented several separation heuristics for SECs, blossom, comb, and clique-tree inequalities, along with some new conditions under which shrinking can be safely performed.
- Naddef and Thienel [29] presented new heuristics for comb, clique-tree, path, bipartition, and ladder inequalities. They are based on shrinking and local search.
- Applegate *et al.* [1] analysed in depth certain data structures that can be used to speed up various SEC, blossom, and comb heuristics.
- Boyd *et al.* [30] and Cook *et al.* [31] presented heuristics for domino-parity inequalities, based on shrinking the support graph to make it planar, and then running the algorithm of Letchford [24].

Finally, we mention two “nonstandard” heuristics for separation: the “small instance” approach of Christof and Reinelt [32] and the “local cuts” approach of Applegate *et al.* [1]. Both of them begin by shrinking the support graph down to a tiny size. The small instance approach then searches through a list of inequality “templates,” whereas the local cuts approach solves a series of tiny STSP instances to generate a cutting plane.

Separation Routines for the ATSP

In the section titled “The Asymmetric Traveling Salesman Polytope,” we mentioned that every valid inequality for STSP(n) can be converted into a valid inequality for ATSP(n), simply by replacing x_e with $x_{ij} + x_{ji}$ for all edges $e = (i, j) \in E$. This implies that every separation algorithm for the STSP can be used, as a “black box,” for the ATSP as well. To this end, given the ATSP (fractional) point $x^* \in [0, 1]^{|A|}$, one first defines the undirected counterpart $\tilde{x} \in [0, 1]^{|E|}$ by means of the transformation

$$\tilde{x}_e := x_{ij}^* + x_{ji}^* \quad \text{for all edges } e = (i, j) \in E,$$

and then applies the STSP separation algorithm to $\tilde{x}$. On return, the most violated STSP inequality detected is transformed into its ATSP counterpart, both inequalities having the same degree of violation.

The above approach to separation can be used only for *symmetric* ATSP inequalities. The only article of which we are aware that addresses separation for *asymmetric* ATSP inequalities is Fischetti and Toth [33]. These authors presented an exact separation algorithm for D_k^+ and D_k^- inequalities, based on partial enumeration of suitable node sequences $(i_1, \dots, i_k)$, for $k = 2, \dots, n - 1$. To prune the search, upper bounds on the violation of the inequalities are used. The authors also presented a heuristic separation algorithm for odd CAT inequalities, based on the computation of minimum weight odd circuits in an auxiliary “incompatibility graph.” This separation algorithm can be viewed as a specialized version of a scheme proposed by Caprara and Fischetti [34] for the separation of a subclass of Chvátal-Gomory cuts for general integer programming problems.

EXACT TSP ALGORITHMS

In this section, we review the main exact algorithms for the TSP that are based on the use of strong valid inequalities as cutting planes. We assume that the reader is already familiar with the basic ideas of branch-and-bound and branch-and-cut, which are covered in the articles titled **Branch-and-Bound Algorithms** and **Branch and Cut**, respectively in this encyclopedia.

Exact Algorithms for the STSP

The first article to propose the use of linear programming to solve the STSP was Dantzig *et al.* [6] in 1954. The authors computed an optimal tour through 49 cities in the United States, an impressive achievement at the time. The cutting planes, mainly SECs, were identified by eye. Moreover, the authors used a limited form of branching, even though branch-and-bound had not been invented at the time.

In the 1970s and 1980s, several articles appeared in which larger TSP instances were solved by the same approach, but with the addition of other kinds of cutting planes, such as blossom and comb inequalities. A good example is Grötschel [35], which details the solution of a 120-city problem.

The next step was the development of what is now called the *cut-and-branch* approach, in which a cutting plane algorithm is used to create a strong LP relaxation, which is then fed into a branch-and-bound solver. An early example can be found in Crowder and Padberg [26]. This approach was pushed to its limits by Grötschel and Holland [27], who solved instances with up to around 600 cities.

A disadvantage of the cut-and-branch approach is that the integer solution obtained might violate some SECs, in which case they must be added to the formulation, and branch-and-bound must be repeated. The natural solution to this is to run separation algorithms at every node of the branch-and-bound tree. This is the *branch-and-cut* approach of Padberg and Rinaldi [36]. Using this approach, Padberg and Rinaldi solved instances with up to around 2000 cities, using SECs and blossom, comb, and clique-tree inequalities.

The branch-and-cut approach has been further refined, for example, by Naddef and Thienel [29], Applegate *et al.* [1], and Cook *et al.* [31]. The software of Applegate *et al.*, called Concorde, has been made freely available on the web [37]. It is capable of solving instances with tens of thousands of cities to proven optimality. According to Cook *et al.* [31], the domino-parity inequalities and the local cuts are the most effective cutting planes for large instances.

Exact Algorithms for the ATSP

Only two articles concerned with branch-and-cut algorithms for the ATSP have been published: Fischetti and Toth [33] and Fischetti *et al.* [38].

The algorithm of Fischetti and Toth [33] is based closely on the Padberg and Rinaldi [36] framework. There are, however, some important details:

1. A sophisticated scheme is used for pricing (column generation), which exploits the fact that a directed tour cannot select arcs with negative reduced cost in an arbitrary way.
2. Asymmetric inequalities— D_k^+ , D_k^- and odd CAT inequalities—are used in addition to symmetric ones.
3. Rounds of violated inequalities are added when possible, rather than only the most violated one.
4. A primal heuristic, based on detecting Hamiltonian cycles in the (directed) support graph, is extensively used.

The resulting algorithm solved to optimality most of the ATSP instances in the literature.

Fischetti *et al.* [38] proposed some enhancements to the Fischetti–Toth algorithm. In particular, the branching variable in Ref. 33 was selected among those closest to 0.5 (a classical criterion) while in Ref. 38, priority for branching was given to the variables that have been persistently fractional in the last (consecutive) LP optimal solutions at any branching node.

Fischetti *et al.* [38] also tested a rather different approach, in which the ATSP instance is transformed to an STSP instance, which is then solved by the STSP solver Concorde mentioned in the previous section. They tested two different transformations: the one due to Karp [5], in which an ATSP instance with n nodes is converted to an STSP instance with $3n$ nodes, and the one due to Jonker and Volgenant [39], in which the resulting STSP instance has only $2n$ nodes. The computational results in Ref. 38 show that this alternative approach is competitive with (although not superior to) the approach in Ref. 33.

We close this discussion by pointing out an important difference between the STSP and the ATSP. In the case of the STSP, branch-and-cut is currently the undisputed best approach for solving large-scale instances. This is not so with the ATSP: for some instances, such as randomly generated instances with no correlation between c_{ij} and c_{ji} , combinatorial algorithms based on *assignment relaxations* can perform as

well or even better. This is discussed in more detail in the article titled **Combinatorial Traveling Salesman Problem Algorithms** in this encyclopedia.

Park, New Jersey

In applied probability, “matrix analytic methods” is the name given to a body of unified algorithmic techniques exploiting probabilistic structure and based on nonlinear matrix iterations for analyzing large classes of structured Markov chains and Markov renewal processes. Although there have been sporadic uses of matrix-based methods in the literature [1–4], the credit for initiating a systematic theory with wide scope and leading to reliable algorithms must go to Marcel F. Neuts whose two papers [5,6], which respectively analyzed two major classes of models known as the $M/G/1$ and the $GI/M/1$ types, marked the clear beginnings of that theory. The approach has since been embellished with many generalizations, faster and better algorithms, and more importantly many credible applications to practical problems. This is a brief overview of the subject with a historical perspective concentrating primarily on major milestones along its growth. For a detailed treatment, we refer to the following texts: Neuts [7,8]; Latouche and Ramaswami [9]; and Bini *et al.* [10]. The beginner may find Latouche and Ramaswami [9] to be the most accessible. Two useful tutorials on the topic are Ramaswami [11] and Alfa [12].

THE BASIC STRUCTURES

Matrix analytic methods deal with two-dimensional, countable state space Markov renewal processes of which the first coordinate has a skip-free structure in at least one direction. Denoting a general state by (i, j) ,

$i \in N = \{0, 1, \dots\}$ and $1 \leq j \leq m < \infty$ and grouping states into “levels” $\mathbf{i} = \{(i, 1), \dots, (i, m)\}$, there are three structures that are covered:

- The **M/G/1** type: Here any one-step transition from a level $\mathbf{i}$ can occur only into levels $\mathbf{i} - \mathbf{1}$ and above; in other words, the model is skip-free downward in levels.
- The **GI/M/1** type: Here any one-step transition from a level $\mathbf{i}$ is restricted to levels up to $\mathbf{i} + \mathbf{1}$; in other words, the model is skip-free upward in levels.
- Quasi-Birth-and-Death (QBD): Here one-step transitions from $\mathbf{i}$ are restricted to levels $\mathbf{i} - \mathbf{1}, \mathbf{i}, \mathbf{i} + \mathbf{1}$; clearly, such a process is skip-free in levels in both directions.

In each of these cases, it is further assumed that the transition structure has a spatial homogeneity; specifically, except for the boundary level $\mathbf{0}$, the transition probabilities from level $\mathbf{i}$ to $\mathbf{k}$ depend on the values of i and k only through the difference $i - k$. Thus, in the case of Markov chains, the three models above correspond respectively to block partitioned transition matrices of the forms given below.

$$\begin{bmatrix} B_0 & B_1 & B_2 & B_3 & \dots \\ A_0 & A_1 & A_2 & A_3 & \dots \\ 0 & A_0 & A_1 & A_2 & \dots \\ 0 & 0 & A_0 & A_1 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix},$$

$$\begin{bmatrix} B_0 & A_0 & 0 & 0 & \dots \\ B_1 & A_1 & A_0 & 0 & \dots \\ B_2 & A_2 & A_1 & A_0 & \dots \\ B_3 & A_3 & A_2 & A_1 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix},$$

$$\begin{bmatrix} B_0 & A_0 & 0 & 0 & \dots \\ A_2 & A_1 & A_0 & 0 & \dots \\ 0 & A_2 & A_1 & A_0 & \dots \\ 0 & 0 & A_2 & A_1 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}$$

The names come from their scalar versions, which correspond respectively to the Markov chains in the ordinary $M/G/1$, $GI/M/1$, and birth–death models. In the Markov renewal case, the transition kernels inherit the above structures with convolutions replacing matrix multiplication. Also, continuous time models have an analogous treatment [9].

Some comments are immediately in order:

- (i) The coordinate j itself could be a vector of states; thus, the process may actually be multidimensional; (ii) extensions could be made trivially for processes like multiserver queues wherein the underlying structure holds only after a finite number of levels [9]; (iii) the restriction of the second coordinate to a finite set was necessitated only by early methodology based on Perron Frobenius results for finite dimensional matrices and is not really needed.

THE $M/G/1$ TYPE

We assume all models under consideration to be irreducible. It is well known [13] for the ordinary $M/G/1$ queue that the key quantity to be analyzed is the busy period. Denoting by g_k the probability that starting in 1 the Markov chain makes its first visit to 0 at step k , a simple conditioning argument shows that $g^*(z) = \sum z^k g_k$ must satisfy the equation $g^*(z) = \sum_{n=0}^{\infty} z a_n [g^*(z)]^n$, and furthermore that in the ergodic case the eventual probability of visiting 0 which is $g = g^*(1)$ is 1 and the mean time to visit 0 which is $g^{*(1)}$ is finite. The classical approach, however, treated the equation as $g^*(z) = z a^*(g^*(z))$, where $a^*(\cdot)$ is the generating function of $\{a_i\}$ and proceeded based on complex analysis via Rouché’s theorem. Once $g^*(z)$ is determined, one can immediately determine the return time distribution to level 0 to be given by $\sum_{n=0}^{\infty} z b_n [g^*(z)]^n$. These enabled a detailed analysis in terms of $g^*(z)$. In the ergodic case one can also get a simple recursion due to P.J. Burke for steady state probabilities by rearranging the steady state equations slightly ([8], pp. 16–17).

The approach in Neuts’ articles [5,14] can be considered to be a direct generalization of these ideas. For the first passage time from

level 1 to level 0, the natural quantity to be considered is the conditional probability $g_{ij}(k)$ that, given the initial state is $(1,i)$, the first visit to 0 occurs at step k through a visit to the specific state $(0,j)$; the associated matrix generating function $G^*(z) = \sum_{k=1}^{\infty} z^k G(k)$, where $G(k)$ is the $m \times m$ matrix of elements $g_{ij}(k)$. With $G = G^*(1)$ yielding the probabilities of eventual entry into 0, we get the equations

$$G^*(z) = z \sum_{n=0}^{\infty} A_n [G^*(z)]^n, \quad G = \sum_{n=0}^{\infty} A_n G^n. \quad (1)$$

From this, it would follow easily that the return times to level 0 are governed by the generating function $B^*(z) = \sum_{n=0}^{\infty} z B_n [G^*(z)]^n$. In the Markov chain case, it was advocated to first compute G , then compute $B^*(1)$ from which the steady state vector $\mathbf{x}_0$ for level 0 could be computed up to a scalar multiple, and then use a Gauss–Seidel iteration scheme for higher steady state probabilities; see Neuts [8] for a detailed treatment.

With regard to the equations in (1), two different approaches were taken: (i) Perron–Frobenius theory for nonnegative matrices; (ii) fixed point theorems from functional analysis. It is somewhat interesting to note that the latter already showed that the finiteness of the second coordinate was really not germane to the structure [11,15].

For the computation of G and various moments of first passage times, and so forth, the recommended method was one of iterations based on a bootstrap. Thus for G , one could implement the iterations $G \leftarrow \sum A_n G^n$ starting with the zero matrix. Neuts showed that these iterates are monotonically increasing to the required solution. Several variants of the basic equation were considered, as also the Newton scheme. Neuts demonstrated that the Newton scheme, though quadratically convergent, is computationally too intensive to yield gains in computing time. Later, Ramaswami [16] developed several monotone sub-Newton schemes, but no major breakthrough really occurred for a long time. The present state of the art is to use the logarithmic and cyclic reduction algorithms; refer to the section titled “Algorithms.”

Some notable early applications of the theory can be found in the articles of Neuts [14,17], Ramaswami [18], Lucantoni [19], and others. In his work [14] Neuts revisited the semi-Markov queue and showed that an analysis not incurring any of the unwanted and unverifiable technical assumptions such as those of [1,20] could indeed be made. In Ref. 17, he demonstrated how for a variety of classical queues and other applied probability models, complex variable methods based on Rouché's theorem could be avoided in favor of stable algorithms. Ramaswami [18] generalized the standard $M/G/1$ queue to the case of a batch Markov arrival process, and provided a unified approach with a substantial matrix generalization of the celebrated Pollaczek–Khinchin formula for the stationary waiting time distribution. Lucantoni [19] cast Ramaswami's results in a more convenient notation and added a few additional results of his own. Chaudhury *et al.* [21] provided a detailed transient analysis of this model. Besides these, a large set of examples of the $M/G/1$ paradigm have been analyzed, and many papers in journals like those of the IEEE have appeared applying them to queueing models for computer and communication systems. Even the early monograph of Neuts [8] has numerous examples falling under the matrix $M/G/1$ paradigm.

Early approaches [1,2] had in some sense considered generalizing the classical approach based on the scalar equation $g^*(z) = za^*(g^*(z))$ to matrix-based equations. But with the Rouché's theorem-based approach as guide, they had, instead of the equations in (1), considered the scalar equation in u given by $\det[uI - zA^*(u)] = 0$, which one can quickly identify as the equation for the eigenvalues of $G^*(z)$. Unfortunately, those attempts entailed the difficult questions related to uniqueness of eigenvalues and availability of enough independent eigenvectors one inevitably encounters in spectral decomposition [22].

Returning to Neuts' matrix analytic approach, the literature on the paradigm also included many methodological advances. These include the following: (i) forging connections of the approach with the theory of ladder heights and Wiener–Hopf methods,

Asmussen being a main driver; see Asmussen [23] and references therein; (ii) probabilistic interpretation of various algorithms, notable being the work of Latouche [24] which provided an interesting and useful interpretation of a linear bootstrap algorithm for G ; (iii) Ramaswami's development of a recursive scheme avoiding the arduous Gauss–Seidel iterations for steady state probabilities [25]; (iv) uniformization-based schemes that avoid tedious matrix numerical integrations for $\{A_n\}$, and so on, in various models, Lucantoni and Ramaswami [26].

In this context, it is worth noting that the phase-type distributions introduced by Neuts [27] (see Ref. 7, Chapter 2) and related point process models like the batch Markov arrival process (BMAP) [28] (see also Refs 19 and 9, Chapter 3) provided a tractable set of general models engineers could use and helped to propel the use of matrix analytic methods in diverse applications related to computer and communication engineering as well as to other areas like insurance risk.

THE GI/M/1 TYPE

The classical ergodic $GI/M/1$ type Markov chain is skip-free upward and is known to have a geometric steady state distribution $x_n = x_0 r^n$, where r is the unique solution in $(0, 1)$ of the equation $r = \sum_{n=0}^{\infty} r^n a_n$. As Neuts was able to generalize the $M/G/1$ type to the matrix case, it was natural for him to consider the matrix analog of the $GI/M/1$ type. Neuts [6] demonstrated that the resulting model exemplified by the second matrix structure in the displayed paradigms has a steady state distribution of a matrix-geometric form $\mathbf{x}_n = \mathbf{x}_0 R^n$, where R is the minimal nonnegative solution of the matrix equation

$$R = \sum_{n=0}^{\infty} R^n A_n, \quad (2)$$

and that the vector $\mathbf{x}_0$ could be determined up to a scalar multiple from the first partitioned steady state equation, which reduces to $\mathbf{x}_0 = \mathbf{x}_0 \sum_{n=0}^{\infty} R^n B_n$. The approach of Neuts [6] was purely *ad hoc*, and the mathematical details built on a skillful use of Perron–Frobenius

theory. Neuts quickly followed through with another article [29], providing an interpretation for the matrix R as comprising of the expected number of visits to $(n+1, j)$ by the Markov chain in a return time to level $\mathbf{n}$ starting at (n, i) . Soon a monograph of Neuts [7] emerged providing a detailed account of the theory and numerous example applications. The monograph caught the attention of the applied probability community in a significant way establishing matrix analytic methods as a major set of tools in applied probability.

The quantity R was extended to a kernel $R(z, s)$ related to the transient analysis of the models by Ramaswami [22], who also showed it to satisfy the nonlinear matrix equation

$$R(z, s) = z \sum_{n=0}^{\infty} [R(z, s)]^n A_n(s), \quad (3)$$

and to have the interpretation as the transform of a taboo Markov renewal function yielding the expected number of visits to a higher level at all time points during a return time to the current level; we have, $R = R(1, 0)$. With the power of hindsight, one can say that this article paved the way later on for the transient analysis of many models of the matrix-geometric type, including of stochastic fluid flows. A later article of Ramaswami [11] developed an entirely probabilistic approach to the matrix-geometric results based on the elementary theory of terminating renewal processes, thereby also removing the shackle of finiteness of the second coordinate. An important result pertaining to the infinite dimensional extension is the work of Ramaswami and Taylor [30] demonstrating the celebrated product form result for Jackson networks as a structural result in an operator-geometric characterization.

As with the $M/G/1$ paradigm, the literature abounds in numerous exemplifications of the $GI/M/1$ type structure and its value to applications. Among the theoretical developments, a particularly important one is the characterization by Asmussen (see Ref. 31 and references there) and by Ramaswami [32] using entirely different arguments, of the stationary waiting time distributions in many phase type queues as being of phase

type. There has also been work on several special cases where the matrix R (or the matrix G in the case of the $M/G/1$ type) could be obtained explicitly or shown to have a simplified structure that leads to more efficient computations; for example, Ramaswami and Lucantoni [33], Latouche and Ramaswami [34,35].

To the list of theoretical developments, we should add Ramaswami's duality results [36], which helped to demonstrate a unifying theme between the $M/G/1$ and $GI/M/1$ type models via time reversal. The close resemblance of the nonlinear equations for $G^*(z)$ and $R^*(z)$ begged a result that would connect them, but had eluded researchers for long. The simple intuition behind Ramaswami's finding, as noted in Ref. 37, is that a first passage path from $\mathbf{n} + \mathbf{1}$ to $\mathbf{n}$ in an $M/G/1$ type model when reversed in time gives a taboo upward path from $\mathbf{n}$ to $\mathbf{n} + \mathbf{1}$ avoiding level $\mathbf{n}$ in the time reversal, which is a model of the $GI/M/1$ type. In addition to unifying the results on the two major paradigms, this duality result has been found to be of algorithmic value. Unlike G , the matrix R is not substochastic or stochastic; the corresponding nonlinear equation is usually not a contraction either. Thus iterative methods for R tend to be more difficult than those for G . A simple way to avoid problems is to compute the G matrix of the time reversed dual and then evaluate the needed R matrix using a simple duality transformation.

QBDs AND FLUID FLOWS

The final structure in the set of three paradigms, the QBD, falls in the intersection of the $M/G/1$ and the $GI/M/1$ paradigms and is a favorite of Markov modelers in engineering. The $M/M/1$ queue in a random environment [7] is an example. For QBD's, both $G^*(z)$ and $R^*(z)$ exist, and furthermore the equations governing them reduce to matrix quadratic equations. The QBD thus becomes a special case of the Neuts' paradigms. We note here that matrix-geometric steady state distributions had been obtained earlier for a special case of the QBD by Evans [3], and for the

general case of the QBD in the unpublished dissertation of Wallace [4]; unfortunately, neither authors had developed the approach to its full potential.

Though the QBD is a special case, it has a major importance of its own. Ramaswami [38] demonstrates that the QBD is not only a special case of the $M/G/1$ and the $GI/M/1$ types, but also its theory subsumes those of the more general paradigms. The key to this is a demonstration that, with a suitable embedding in a process with an enlarged state space, the more general paradigms can be realized within a QBD and analyzed via the QBD.

Another reason for the importance of the QBD arises from its connection to Markovian stochastic fluid flows. Asmussen [39] developed a phase type characterization for the steady state distribution of stochastic fluid flow models along with a set of algorithms resembling the linear iterations; his approach, however, was not based on the matrix analytic theory of Neuts. However, Ramaswami [40] made a connection of stochastic fluid flow models to discrete time QBDs and developed quadratically convergent algorithms based on the QBD for steady state results. Ahn and Ramaswami [41] developed this idea further to obtain a complete transient analysis and also developed a powerful quadratically convergent algorithm [42]. This work has generated much interest, and many researchers—Badescu, Bean, Latouche, O'Reilly, Remiche, Soares, Stanford, Taylor, Takine, *et al.*—have since made many additional contributions. Albeit in a different context, for continuous level problems, Sengupta [43] appears to be the first to see a connection with matrix-geometric type models.

ALGORITHMS

We noted that early attempts at numerics were via bootstrapping on the nonlinear matrix equations. The technique provided only linear convergence and could converge very slowly as exemplified for instance in Daigle and Lucantoni [44]. Hence, the need for efficient algorithms was pressing but not

much progress could be made since familiar accelerations of numerical analysis like the Newton scheme either did not yield good results for computational time or were violating the constraints needed such as non-negativity of the solutions.

A major breakthrough occurred in the field with the logarithmic reduction algorithm of Latouche and Ramaswami [45]. The idea was a simple one and had been proposed by Ramaswami in answer to the Daigle and Lucantoni problem [44] and tried out successfully: “If one knew R^2 in a QBD, one could determine R from a linear equation; so, get R^2 which has a smaller spectral radius (it is when the spectral radius of R is near 1 that one has problems of convergence); and we can get R^2 by considering the embedded QBD on levels $\{0, 2, 4, \dots\}$. Indeed, this idea could be iterated a few times until an equation with a nice behavior obtains.” However, no formal analysis of the method was done for long.

During a visit of Latouche to Bellcore, Latouche and Ramaswami worked together and demonstrated in an article [45] that analyzing the sequence of embedded QBDs on levels $\{0, 2^n, 2 \times 2^n, 3 \times 2^n, \dots\}$ does indeed lead to an explicit expression for G , and that in turn provides an approximation with quadratic convergence. Enabling the proof were two different pieces of earlier work of the authors: analysis of the linear algorithm by Latouche [24] and a duality result of Ramaswami and Neuts [46], the former providing the probabilistic interpretation for the steps and the latter automatically implying quadratic convergence of the scheme. The name of the algorithm arises from the fact that while the linear algorithm covers in n steps exactly n levels up in a return time to a given level, the present algorithm covers 2^n levels above; thus the reduction in time in covering excursions to higher levels is reduced by a logarithmic factor. For mathematical details of the algorithm, we refer the reader to Latouche and Ramaswami [9, 45]. The algorithm has been analyzed by Ye [47] who has established its numerical stability and also made a valuable addition to find a solution to a (very rare) problem encountered by the method.

In the form in which it was derived in the article [45], it was not easy to generalize the algorithmic steps of the logarithmic reduction algorithm to the $M/G/1$ type. However, two able numerical analysts Bini and Meini from Pisa quickly established connections of the logarithmic reduction algorithm to procedures called *cyclic reduction* and *even-odd reduction* in linear algebra and developed, in a series of articles (see Refs 48 and 49), a quadratically convergent algorithm for the more general $M/G/1$ type of models. The basic tool of their analysis is Schur complementation for Toeplitz systems. Recent papers of Hunt [50] and Bini *et al.* [51] show, however, that the Bini–Meini method is equivalent to a logarithmic reduction with a slightly different set of successive filtering of the levels into the sets of levels $\{0, 1, 1 + 2^n, 1 + 2 \times 2^n, 1 + 3 \times 2^n, \dots\}$. We hasten to note, however, that the contributions of Bini and Meini extend far beyond the algorithm and cover numerous enhancements to it, including efficient implementations using fast Fourier techniques. For a detailed discussion and extensive bibliography, we refer the reader to the recent monograph by Bini *et al.* [10].

OTHER DEVELOPMENTS AND EXTENSIONS

The above discussion covers the core theory and algorithms, but the contributors and contributions to matrix analytic methods are much more numerous than what we have been able to cite in a brief discussion. The objective of this section is to highlight some other major players and developments in the field with due apologies for omissions inadvertent or necessitated by brevity. For specific work not cited in the bibliography, see the referenced texts. More recent ones may be found easily through a web search.

Finite state models. The QBD with a finite number of levels is exceptional in that it leads to a characterization of its steady state vector as a sum of two matrix-geometric terms [52]. Besides this, other models rarely result in interesting near closed form formulae. However, the basic ideas of matrix analytic methods can be employed efficaciously as shown

for instance by Gaver, Jacobs and Latouche. One may also develop efficient algorithms based on the idea of even-odd reduction for steady state probabilities and first passage times. Details and references may be found in the book of Latouche and Ramaswami ([9], Chapter 10). In this context, we wish to note that the Russian school led by Professor P. Bocharov had made much progress on finite state space models along the lines of matrix analytic methods, but the work unfortunately went unnoticed outside the former Soviet Union.

Spatial inhomogeneity. The basic ideas extend to processes without spatial homogeneity, but at the expense of complexity in that each level has its own R or G matrix [11]. While this makes a general theory difficult, major inroads have been made by Taylor and his colleagues, with Bright and Taylor [53] being a noteworthy beginning for systematic efforts.

Non-skip-free models. Moran’s dam considered in Neuts [17] is an early example of a model that does not have a structure amenable to matrix analytic methods, but could be turned into one by a clever reblocking of the states. The literature has a number of examples where such reblocking is employed, and among them we draw particular attention to the work of Gail *et al.* [54], which attempts to unify a lot of special cases.

Tree structured models. Underlying matrix analytic methods is the idea of a “neighbor” class of states and connectivity restrictions among them. Thus, the basic algorithms could be extended to instances where levels are not restricted to be integers but could be more general like nodes in a tree. Such models arise, for example, in queues with the LIFO discipline. Yet, the extension is not routine in that additional structures are obtained that significantly simplify computations. Yeung and Sengupta [55] and Takine *et al.* [56] are credited for this important discovery, and two often cited articles are Yeung and Alfa [57] and He and Alfa [58]. The teams Bini, Meini, and Latouche and Blondia and Van Houdt have provided efficient algorithms geared to these specific structures.

Retrial queues. A renewed interest due to call centers has spawned off much recent work on retrial queues with orbiting customers. There are two early articles in this area using matrix analytic methods [59,60]. For many others, see the various proceedings of the Conferences on Retrial Queues organized by Artalejo and Krishnamoorthy [61].

Discrete time models. Many practical queueing systems operate in discrete time, and discrete time queues present opportunities for exploring additional structures and nuances. Indeed, the early applications of matrix analytic methods were to a set of discrete time queues; see the papers of Neuts with Heimann [62] and Dafermos [63] in the Naval Research Logistic Quarterly. Discrete time queues continue to be an active area of research with some notable work in this area by Alfa and his colleagues.

Related methods. Interconnections with established methods of mathematics abound. Thus, earlier spectral methods based on eigenvalues, and others, have new interpretations in terms of the matrix analytic structure; these have been explored in depth by many researchers like Hantler and Taylor. A prescient work in this area is that of Neuts [64] related to the importance of the largest eigenvalue of the matrix R as a major determinant of path behavior, and the highly used “equivalent bandwidth” [65] for packet queues based on fluid flow models can now be directly related to that through the connection of the fluid model to QBDs. Researchers like Grassman and Heyman have established connections with the theory of censoring for Markov chains, while Akar and Sohraby have approached matrix analytic methods via an invariant subspace approach. Lipsky approached the Markov chain problems here through a purely linear algebraic approach. These connections add greater luster to the area and provide additional perspectives.

Real-world applications. Matrix analytic methods have been applied to many real-world problems in computer performance and communications engineering, and related articles may be found notably in *Performance Evaluation*, *Queueing Systems*, and the IEEE journals. New applications are found

in insurance risk theory and mathematical finance. These are too numerous to list individually, and we cite only a few simple examples here [66–68] to highlight the continuing relevance of the methods to modern day engineering.

Numerical analysis. Matrix analytic methods have gained much from classical applied mathematics and linear algebra. It is therefore a delight to see the field returning the favor by way of new tools. Examples of these are the extensions by Bini *et al.*, of the cyclic reduction methods for solving matrix polynomial equations efficiently [69], as well as the emerging new algorithms by Guo, Higham, Bini, and others (see Ref. 70 for an example) for algebraic Riccati equations. The latter is a take-off from Ramaswami’s work on fluid flow models that essentially involves turning a Riccati equation into a matrix quadratic.

Software. A major effort has been launched by the researchers Bini, Steffé, and Meini in Pisa and Van Houdt in Antwerp to develop downloadable software for the key algorithms underlying matrix analytic methods. For details on these, refer to [71].

Playing a significant role in the rapid development of matrix analytic methods has been a series of international MAM conferences starting with the one organized by Chakravathy and Alfa in 1995. So far, a set of six conferences have taken place, and their proceedings contain many interesting papers. These conferences have enabled the community of researchers to interact frequently, disseminate results faster, and exchange ideas.

What has been summarized here is the achievement of a large community of colleagues who have generously shared their ideas and research. We dedicate this note to them in deep friendship and gratitude.

MATRIX-GEOMETRIC DISTRIBUTIONS

DIETER BAUM

of Computer Science,
University of Trier, Trier,
Germany

INTRODUCTION

In this article, matrix-geometric distributions are introduced by emphasizing the significance of structure. We use capital letters for matrices in the following, for example, I_k for the identity (or unit) matrix of order k , O for the null matrix (of any order), and bold face capital letters for matrices in block form. Row vectors are typed as bold face lowercase letters, in particular $\mathbf{o} = (0, 0, \dots)$, $\mathbf{e} = (1, 1, \dots)$, where subscripts may indicate lengths. Transpose vectors or matrices are marked by a superscript T .

Let ξ denote a discrete random variable defined on a lattice $\{x_{nj}\}_{n \in \mathbb{N}_0, j \in \{1, \dots, m\}}$, the rows of which form a countable family $\{\mathbf{x}_n\}_{n \in \mathbb{N}_0}$ of m -dimensional real vectors $\mathbf{x}_n = (x_{n1}, \dots, x_{nm})$ (m may be infinite). Set $\mathbb{P}(\xi = x_{nj}) = \pi_{nj}$, $\boldsymbol{\pi}_n = (\pi_{n1}, \dots, \pi_{nm})$. The distribution of ξ is said to be of *matrix-geometric type* if there is some constant square matrix R of order m such that

$$\boldsymbol{\pi}_{n+s} = \boldsymbol{\beta} \cdot R^n \quad \forall n \geq 0, \quad 0 \leq s < \infty \quad (1)$$

($\boldsymbol{\beta} \in \mathbb{R}^m$ a constant vector). Obviously, for $m = 1$ and $s = 0$ Equation (1) resembles the customary expression $\mathbb{P}(\xi = n) = (1 - \rho) \cdot \rho^n$ for a geometric random variable with parameter ρ . Within the framework of vector state Markov models, that is, $m > 1$, the lattice is made up by pairs $x_{nj} = (n, j)$, $n \in \mathbb{N}_0$, $j \in \{1, \dots, m\} = E$. The number n in (n, j) —or, occasionally, the entire *macrostate* $\mathbf{n} = ((n, 1), \dots, (n, m))$ —is termed *level*. An irreducible recurrent Markov process with an

invariant vector $\boldsymbol{\pi} = (\pi_0, \pi_1, \dots)$ satisfying Equation (1) is called *matrix-geometric Markov process*, and the techniques to solve for this distribution by constructing the matrix R are classified under the general appellation *matrix-geometric methods*. Correspondingly, stochastic models defining a matrix-geometric Markov process are called *matrix-geometric models* or *models of matrix-geometric structure*.

In what follows, we use the term *characteristic matrix* to designate the transition probability matrix P of some discrete time Markov process (Markov chain), or rather the generator matrix Q in the continuous time case. A vector state Markov process X is called *skip-free upward in levels* if the elements $w_{(n_1, i); (n_2, j)}$ ($n_1, n_2 \in \mathbb{N}_0, i, j \in E$) of its characteristic matrix W satisfy $w_{(n, i); (n+k, j)} = 0 \quad \forall k > 1$, and is called *spatially homogeneous* from ℓ on if $w_{(n_1+k, i); (n_2+k, j)}$ does not depend on k for $n_1 \geq \ell, n_2 \geq \ell$. The grouping of state probabilities π_{nj} for $n \geq 1$ as $\boldsymbol{\pi}_n = (\pi_{n1}, \dots, \pi_{nm})$ induces a partitioning of W , converting it into a block matrix $\mathbf{W}$. Assume that X is spatially homogeneous from $\ell = 2$ on and irreducible recurrent (as well as aperiodic in the discrete time case). Then, as we shall show, the matrix-geometric solution (Eq. 1) is a consequence from the lower block Hessenberg structure of $\mathbf{W}$ which results from the skip-free upward property

$$\mathbf{W} = \begin{bmatrix} B_{00} & B_{01} & O & O & O & \dots \\ B_{10} & B_{11} & A_0 & O & O & \dots \\ B_{20} & B_{21} & A_1 & A_0 & O & \dots \\ B_{30} & B_{31} & A_2 & A_1 & A_0 & \dots \\ B_{40} & B_{41} & A_3 & A_2 & A_1 & \dots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}. \quad (2)$$

Equation (2) represents the main structure of interest. The matrices $B_{n_1 n_2}$ ($n_1 \in \mathbb{N}_0$, $n_2 \in \{0, 1\}$) are called *boundary matrices*. B_{00} is a square matrix of order $m_0 \in E$, B_{01} an $m_0 \times m$ matrix, and for $n_1 \geq 1$ the $B_{n_1 n_2}$ represent $m \times m_0$ matrices for

$n_2 = 0$, and $m \times m$ matrices for $n_2 = 1$. The corresponding states are called *boundary states*, all other *repeating states*. Since Equation (2) resembles the transition matrix of the embedded Markov chain at arrival instants of a $GI/M/1$ queueing model, it is termed *canonical $GI/M/1$ form*, and W is said to be of *$GI/M/1$ type* (the *repetitive upper Hessenberg structure* of $M/G/1$ type matrices does not lead to a matrix-geometric solution).

We mention three special examples:

1. The simple $M/M/1$ queueing system in equilibrium, leading to a continuous time Markov process with geometric steady-state distribution. Let N_t denote the number of customers resident at time t , and λ and μ the mean arrival and service rates, respectively. Then, given that $\rho = \frac{\lambda}{\mu} < 1$, $\lim_{t \rightarrow \infty} \mathbb{P}(N_t = n) = \pi_n = \beta \cdot \rho^n \quad \forall n \geq 0$ with $\beta = \pi_0$. State transitions take place between neighboring states only, and so the infinitesimal generator Q of the process $\{N_t : t \geq 0\}$ possesses a tri-diagonal structure with “repeating rows”, describing a birth-and-death queueing system. It is this tri-diagonal repetitive structure (resembling a lower Hessenberg form for $\ell = 1$) that lends to the geometric stationary distribution. More generally, given an irreducible recurrent continuous time Markov process on a denumerable state space with generator

$$Q = \begin{bmatrix} b_0 & a_0 & 0 & 0 & 0 & \dots \\ a_2 & a_1 & a_0 & 0 & 0 & \dots \\ 0 & a_2 & a_1 & a_0 & 0 & \dots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix},$$

the limiting state probabilities satisfy $\pi_n = \pi_{n-1} \frac{a_0}{a_2} = \pi_0 \left(\frac{a_0}{a_2} \right)^n$ for $n \geq 1$, and the process is ergodic if and only if $a_0 < a_2$. This result, although easily obtained from $\pi Q = \mathbf{o}$ with $\pi = (\pi_0, \pi_1, \dots)$ and $Q\mathbf{e}^T = \mathbf{o}^T$, can be proven by using purely probabilistic arguments from the theory of terminating renewal processes [1].

2. The $M/PH/1$ queueing system as an example for a continuous time matrix-geometric model with $m > 1$. Service periods are times until absorption in a finite state Markov process $\{J_t : t \geq 0\}$ with transient states $1, \dots, m$ and absorbing state $m+1$. Let α describe the “ m -portion” of the initial probability vector $(\alpha_1, \dots, \alpha_m, \alpha_{m+1}) = (\alpha, \alpha_{m+1})$, and $S = [S_{ij}]$ the $m \times m$ matrix of state transition rates among transient states, such that $S_{ii} < 0$, $S_{ij} \geq 0$ for $i \neq j$, and $S\mathbf{e}^T = -\eta^T$, η^T the column vector of absorption rates; then (α, S) is the representation of the phase type distribution (see **Phase-Type (PH) Distributions**). Absorption occurs with probability 1 from any transient state $i \in \{1, \dots, m\}$ if and only if S is nonsingular, and the system assumes equilibrium provided the product of mean service time $\mathbb{E}[H]$ and mean arrival rate λ satisfies $\mathbb{E}[H] \cdot \lambda = \alpha(-S^{-1})\mathbf{e}^T \cdot \lambda < 1$. Given that no group services occur and each service duration is > 0 , we have that $\alpha_{m+1} = 0$. The underlying stochastic process $\{(N_t, J_t) : t \geq 0\}$, where N_t stands for the number of customers resident in the system at time t , is a homogeneous ergodic Markov process on the state space $\{0\} \cup \{(n, j) : n \geq 1, j \in \{1, \dots, m\}\}$ whose infinitesimal generator Q in block form reads

$$Q = \begin{bmatrix} B_{00} & B_{01} & \mathbf{o} & \mathbf{o} & \mathbf{o} & \dots \\ B_{10} & A_1 & A_0 & O & O & \dots \\ \mathbf{o}^T & A_2 & A_1 & A_0 & O & \dots \\ \mathbf{o}^T & O & A_2 & A_1 & A_0 & \dots \\ \vdots & \vdots & \vdots & \ddots & \ddots & \ddots \end{bmatrix}. \quad (3)$$

B_{00} equals the scalar $-\lambda$, B_{01} is the row vector $\lambda\alpha$, B_{10} is the column vector η^T , and the A_i are $m \times m$ matrices given by $A_2 = \eta^T\alpha$, $A_1 = S - \lambda I_m$, and $A_0 = \lambda I_m$. From $\pi Q = \mathbf{o}$, by virtue of the repetitive triangular structure of Q , the following relations result: $\pi_1 \eta^T = \lambda \pi_0$, $\pi_0 \lambda \alpha + \pi_1 A_1 + \pi_2 A_2 = \mathbf{o}$, and $\pi_{n-1} A_0 + \pi_n A_1 + \pi_{n+1} A_2 = \mathbf{o} \quad \forall n \geq 2$.

Exploiting global balance, that is, equating the flow *out* of any macrostate $\mathbf{n} = ((n, 1), \dots, (n, m))$ due to a service completion to the flow *into* the same macrostate caused by an arrival, one is led to $\pi_{n+1}\eta^T = \lambda\pi_n\mathbf{e}^T$ for $n \geq 1$, and this yields $\pi_n(I_m - \mathbf{e}^T\alpha - \lambda^{-1}S) = \pi_{n-1}$. The matrix $\mathbf{e}^T\alpha + \lambda^{-1}S = M$ is indecomposable [2], and $I_m - M$ can easily be proven to be regular. Hence, Equation (1) holds with $s = 1$, $\beta = \pi_0 \cdot \alpha$ and $R = (I_m - \mathbf{e}^T\alpha - \lambda^{-1}S)^{-1}$. By rule of vector-matrix multiplication, Equation (1) implies

$$A_0 + RA_1 + R^2A_2 = O. \quad (4)$$

The matrix R is called *rate matrix*. Two-dimensional Markov processes with block tri-diagonal characteristic matrix have been coined *Quasi birth-and-death* processes (QBDs) by Wallace [3]. Their structure combines the $GI/M/1$ and $M/G/1$ types. The solution (1) for QBDs was first obtained by Evans [4]. The Markov process $\{J_t : t \geq 0\}$ with state space $E = \{1, \dots, m\}$ is termed *phase process*, its states $j \in E$ are called *phases* or *interlevel components*.

3. The $GI/PH/1$ queueing system with an arbitrary interarrival time distribution $F(\cdot)$ that satisfies $\int_0^\infty \tau dF(\tau) < \infty$ and $\lim_{t \downarrow 0} F(t) = 0$ (a generalization of the previous example). The primary ingredient here is the probability transition matrix P of the embedded Markov chain at arrival instants. According to the state grouping, P assumes the lower block Hessenberg form

$$P = \begin{bmatrix} B_0 & A_0 & O & O & O & \dots \\ B_1 & A_1 & A_0 & O & O & \dots \\ B_2 & A_2 & A_1 & A_0 & O & \dots \\ B_3 & A_3 & A_2 & A_1 & A_0 & \dots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix},$$

which leads to the solution (1) for the steady-state probabilities at arrival instants, where R satisfies $\sum_{n=0}^\infty R^n A_n = R$. Once π is known, the

steady-state probabilities at arbitrary time can be computed by applying the key renewal theorem (see Ref. 5 for details).

The investigation of infinite stochastic matrices whose stationary probability distributions assume the matrix-geometric form has been pioneered by Neuts [5–7] and his school. An approach based on terminating renewal processes (as outlined below) originates from the work of Ramaswami [8]. Essentially, in this context, continuous time Markov processes and discrete time Markov processes (Markov chains) can be handled alike. For that reason we may concentrate mainly on the discrete time case.

PROBABILISTIC DERIVATION

To begin with, consider an irreducible aperiodic and spatially homogeneous Markov chain $X = \{(N_v, J_v) : v \in \mathbb{N}_0\}$ on the state space $\mathbb{N}_0 \times E$ whose transition matrix $P = [p_{(n_1, i); (n_2, j)}]_{n_1, n_2 \in \mathbb{N}_0, i, j \in E}$ possesses the *skip-free upward* property, in which case $P = W$ is a lower block Hessenberg matrix as given in Equation (2). Let $p_{(r, i); (s, j)}^{(k)} = \mathbb{P}((N_k, J_k) = (s, j) \mid (N_0, J_0) = (r, i))$ denote the k -step transition probabilities, $P_{r; s}^{(k)} = [p_{(r, i); (s, j)}^{(k)}]_{i, j \in E}$, the corresponding matrices with respect to phases. For $k = 1$ the superscript is omitted. The k -step taboo transition probability from (n, i) to $(n + s, j)$ under taboo of (i.e., avoiding in between) the set of macrostates $T = \{\mathbf{o}, \dots, \mathbf{n}\}$ is designated as $TP_{(n, i); (n+s, j)}^{(k)}$, and its matrix as $TP_{n; n+s}^{(k)}$ ($s \in \mathbb{N}_0$). Owing to the skip-free upward property, the last macrostate in T before visiting $\mathbf{n} + 1$ must be $\mathbf{n}$; therefore, $TP_{(n, i); (n+s, j)}^{(k)} = nP_{(n, i); (n+s, j)}^{(k)}$. By conditioning on the last visit in T before reaching $\mathbf{n} + 1$ at step k , the following is obtained

$$\begin{aligned} P_{(0, i); (n+1, j)}^{(k)} &= \sum_{\ell=1}^m \sum_{h=1}^m \sum_{v=0}^{k-1} P_{(0, i); (n, \ell)}^{(k-1-v)} \cdot P_{(n, \ell); (n+1, h)} \\ &\quad \cdot nP_{(n+1, h); (n+1, j)}^{(v)} \\ P_{0; n+1}^{(k)} &= \sum_{v=0}^{k-1} P_{0; n}^{(k-1-v)} \cdot (P_{n; n+1} \cdot nP_{n+1; n+1}^{(v)}) \end{aligned}$$

$$=: \sum_{v=0}^{k-1} H_{k-(v+1)} \cdot {}_n P_{n;n+1}^{(v+1)} \quad (5)$$

(matrices H_r defined by $H_r = P_{0;n}^{(r)}$). Subsequent epochs of visits to state $(n+1, j)$ after start in (n, ℓ) define, for any fixed n , a delayed renewal process (with some delay time distribution G), which is terminating since X is irreducible. For $n \geq 2$, all these renewal processes are indistinguishable due to the proposed spatial homogeneity, so we may speak of *the* renewal process for $n \geq 2$ and ℓ, j fixed. Since ${}_n p_{(n,\ell);(n+1,j)}^{(v)} =: r_v(n) = r_v$ gives the probability that v is a renewal point, the sequence $\{r_v\}_{v \in \mathbb{N}_0}$ constitutes the delayed renewal density of this process, and $R_k = \sum_{\ell=0}^{\infty} (G * F^{*\ell})_k = \sum_{v=1}^k r_v$ its renewal function, where F_v denotes the distribution function of interrenewal times. As is well known [1,9,10], for an unknown sequence $u = \{u_v\}_{v \in \mathbb{N}_0}$ and a known sequence $\{H_v\}_{v \in \mathbb{N}_0}$, an equation of the form $u_v = H_v + (F * u)_v$ represents a renewal equation whose solution is given by $u_k = \sum_{v=0}^k H_{k-v} \cdot r_v$. Thus, Equation (5) is the solution of a renewal equation. For a terminating renewal process, that is, if $\lim_{v \rightarrow \infty} F_v = F_{\infty} < \infty$, the limiting behavior of this solution takes the form $\lim_{v \rightarrow \infty} H_v \cdot \lim_{k \rightarrow \infty} R_k$ (cf. Çinlar [9]). Consequently, since the k -step probabilities $p_{(0,i);(n+1,j)}^{(k)}$ assume a limit as $k \rightarrow \infty$ (independently from the initial state) Equation (5) yields

$$\pi_{n+1} = \pi_n \cdot R = \pi_1 \cdot R^n \quad \forall n \geq 1, \quad (6)$$

where $R = R_{\infty} = \sum_{v=0}^{\infty} P_{n;n+1} \cdot {}_n P_{n+1;n+1}^{(v)} = \sum_{v=1}^{\infty} {}_n P_{n;n+1}^{(v)}$. It should be noted that similar inferences apply to spatially nonhomogeneous (*level-dependent*) chains, in which case level-dependent rate matrices replace R . Entry R_{ij} of R is the expected total number of visits to state $(n+1, j)$ before the chain returns to $T = \{\mathbf{o}, \dots, \mathbf{n}\}$, given that it started in (n, i) .

The z -transform of v -step taboo transition probability matrices ${}_n P_{n;n+1}^{(v)}$ avoiding $T = \{\mathbf{o}, \dots, \mathbf{n}\}$ is given by $R(z) = \sum_{v=1}^{\infty} r_v \cdot z^v = \sum_{v=1}^{\infty} {}_n P_{n;n+1}^{(v)} \cdot z^v$. Accordingly, the z -transform of the v -step transition probability matrices from $\mathbf{o}$ to $\mathbf{n}$ reads $X_n(z) = \sum_{v=1}^{\infty} P_{0;n}^{(v)} \cdot z^v$. Similar expressions

are valid also for *transient* spatially homogeneous chains, leading to $X_{n+1}(z) = X_n(z) \cdot R(z)$. Observing $P_{n+1+k;n+1} = A_k$ for $n \geq 1$, and ${}_n P_{n;n+1}^{(v)} = \delta_{v1} P_{n;n+1} + (1 - \delta_{v1}) \sum_{k=0}^{\infty} {}_n P_{n;n+1+k}^{(v-1)} P_{n+1+k;n+1}$, where $\delta_{v\mu}$ is the Kronecker symbol, the following expressions are obtained (see Refs. 1 and 8 for details):

$$R(z) = z \sum_{k=0}^{\infty} [R(z)]^k A_k, \quad R = \sum_{k=0}^{\infty} R^k A_k. \quad (7)$$

Note that the result for $z = 1$ in Equation (7) as well as the relation $\pi_n = \sum_{k=0}^{\infty} \pi_{n-1+k} A_k \quad \forall n \geq 2$ are also consequences of Equation (6) when inserted in $\pi P = \pi$. For QBDs, the matrices A_k , for $k \geq 3$, have to be replaced by the null matrix O . For an ergodic chain, the sum $\sum_{n=0}^{\infty} \pi_n = \pi_0 + \pi_1 (I_m + (I_m - R)^{-1}) = \mathbf{p}$ is the steady-state probability vector of the phase process. If $m < \infty$, the inverse $(I_m - R)^{-1} = \sum_{n=0}^{\infty} R^n$ exists, and the spectral radius $sp(R)$ of R is strictly less than 1, which is equivalent to ergodicity [11]; see also [12]. The case $m = \infty$ can be handled by more intricate but, nevertheless, similar techniques (see Ramaswami [8]). In that case the inverse $(I_m - R)^{-1}$ is defined by $(I_m - R)^{-1} = \sum_{n=0}^{\infty} R^n$ (see Seneta [13] for relevant issues on infinite matrices).

The case of a *continuous time* Markov process with spatially homogeneous lower block Hessenberg generator $[q(r,i);(s,j)]_{r,s \in \mathbb{N}_0, i,j \in E}$ (skip-free upwards in levels) can be attributed to the discrete time case by either use of uniformization if $\sup\{|q(r,i);(r,i)| : r \in \mathbb{N}_0, i \in E\} < \infty$, or inspection of the appertaining discrete time Markov chain embedded at transition epochs. This leads to completely analogous formulas: Equation (5), providing Equation (6), has to be replaced by $P_{0;n+1}(t) = \int_0^t (P_{0;n}(t-\tau) \cdot P_{n;n+1}) \cdot {}_n P_{n+1;n+1}(\tau) d\tau$. Instead of z -transforms the Laplace–Stieltjes transforms apply, that is, $X_{n+1}(s) = \int_0^{\infty} e^{-st} P_{0;n+1}(t) dt$ for $Re(s) \geq 0$, resulting in $X_{n+1}(s) = X_n(s) R(s)$ for $n \geq 1$ where $R(s) = P_{n;n+1} \int_0^{\infty} e^{-st} {}_n P_{n+1;n+1}(t) dt$ and $sR(s) = \sum_{k=0}^{\infty} R(s)^k A_k$. The rate matrix

$R = R(0)$ for a continuous time process has to be computed from

$$\sum_{k=0}^{\infty} R^k A_k = O. \quad (8)$$

Examples are queueing systems with bulk services in a random environment [14].

ERGODICITY CONDITIONS

Let $X = \{(N_v, J_v) : v \in \mathbb{N}_0\}$ be the considered irreducible aperiodic Markov chain with state space $\mathbb{N}_0 \times \{1, \dots, m\}$ whose transition matrix $\mathbf{P}$ in block form possesses the skip-free upward property and is spatially homogeneous as in Equation (2). Assume that $m < \infty$, and that the matrix $A = \sum_{k=0}^{\infty} A_k$ is irreducible and stochastic such that it can be interpreted as the transition matrix of some irreducible finite state Markov chain. Let $\psi = (\psi_1, \dots, \psi_m)$ with $\psi_j > 0$ satisfy $\psi A = \psi$ and $\psi e^T = 1$, and define the vector β by $\beta = \sum_{k=1}^{\infty} k A_k e^T$. Then the quantity $\vartheta_X = 1 - \psi \beta^T$ is called *average drift of the chain X*. The following statements hold [8]:

$$\begin{aligned} \vartheta_X > 0 &\implies X \text{ is transient,} \\ \vartheta_X = 0 &\implies X \text{ is null recurrent,} \\ \vartheta_X < 0 &\implies X \text{ is ergodic.} \end{aligned} \quad (9)$$

If $Y = \{(N_t, J_t) : t \geq 0\}$ is a continuous time Markov process on the state space $\mathbb{N}_0 \times \{1, \dots, m\}$, m finite, whose generator $\mathbf{Q}$ in block form is a lower block Hessenberg matrix, the *average drift* of this process is defined as $\vartheta_Y = -\psi \beta^T$, where again $A = \sum_{k=0}^{\infty} A_k$ is assumed to be irreducible and stochastic, and the positive vector ψ satisfies $\psi A = \mathbf{o}$ and $\psi e^T = 1$. In this case again Equation (9), with X replaced by Y , characterizes the ergodicity behavior of the process. Equation (9) reflects the customary conditions for stability of queueing systems: Note that $-\psi \beta^T = \psi (A_0 e^T - \sum_{k=2}^{\infty} (k-1) A_k e^T)$, and consider, for example, the $M/M/s$ queueing system, in which case $m = 1$, $A_0 = \lambda$ (the arrival rate), $A_2 = s\mu$ (the total service rate), and $A_k = 0$ for $k > 2$; then, since $\psi > \mathbf{0}$, $\vartheta_Y < 0$ means $\lambda < s\mu$, the familiar stability condition.

COMPUTATIONAL ASPECTS

In order to solve Equation (1) for π_{n+s} , one has to compute the solution R of Equation (7) in the discrete time case, or rather of Equation (8) in the continuous time case. We concentrate on the discrete time case. Once R has been determined, the computation of the boundary probabilities (assuming $s = 2$) requires to solve

$$\begin{aligned} (\pi_0, \pi_1) \begin{bmatrix} B_{00} & B_{01} \\ \sum_{k=1}^{\infty} R^{k-1} B_{k0} & \sum_{k=1}^{\infty} R^{k-1} B_{k1} \end{bmatrix} \\ = (\pi_0, \pi_1) \end{aligned} \quad (10)$$

subject to $\pi e^T = \pi_0 e_{m_0}^T + \pi_1 \sum_{n=0}^{\infty} R^n e_m^T = \pi_0 e_{m_0}^T + \pi_1 (I_m - R)^{-1} e_m^T = 1$ (the normalization condition).

Simple iteration schemes for solving Equation (7) have first been reported in Ref. 5. Essentially, they are of the form $R^{(0)} = 0$; $R^{(v+1)} = \sum_{k=0}^{\infty} R^{(v)k} A_k$ or, slightly modified, based on the two equations $R = A_0(I_m - U)^{-1}$ and $U = \sum_{k=0}^{\infty} R^k A_{k+1}$, yielding $R^{(0)} = 0$; $R^{(v+1)} = A_0(I_m - A_1)^{-1} + \sum_{k=2}^{\infty} R^{(v)k} A_k(I_m - A_1)^{-1}$ for $v \geq 0$. Note that $I_m - A_1$ is nonsingular since A_1 is substochastic. Matrices R and U are the minimal nonnegative solutions of the above equations (see Theorem 3.4 and Corollary 3.3 in Ref. 8), and if $A = \sum_{k=0}^{\infty} A_k$ is irreducible (as is the case in most applications) the iterates $R^{(v)}$ form a monotonically nondecreasing sequence converging linearly to R [5]. Entry U_{ij} in U is the taboo probability for eventually returning to level $\mathbf{n}$ in (n, j) after start in (n, i) under taboo of lower levels. The speed of convergence of such schemes can become extremely slow as has been demonstrated by Ramaswami [15] and Daigle and Lucantoni [16].

For QBDs, assuming $m < \infty$, let G_{ij} denote the probability that starting from $(n+1, i)$ the chain reaches level $\mathbf{n}$ for the first time in (n, j) . Then, given that the QBD is recurrent and $A = \sum_{k=0}^{\infty} A_k$ is irreducible, G is the minimal nonnegative *stochastic* solution of $G = A_2 + A_1 G + A_0 G^2$. This fact, together with $U = A_1 + R A_2$, gives rise to a stable recursive procedure for calculating G , starting

with $G^{(0)} = I_m$, which yields $U = A_1 + A_0G$ and $R = A_0(I_m - U)^{-1}$ and is considered the most efficient *linear* algorithm for QBDs [1] (complexity is $\approx \frac{14}{3}K \cdot m^3$, K the number of performed iterations). The iterates $U^{(v)}$ and $G^{(v)}$ are substochastic and stochastic, respectively. $G^{(v)}$ is the taboo probability matrix for the events that, starting from some level $\mathbf{n}$, the chain eventually visits level $\mathbf{n} - 1$ under taboo of levels $\mathbf{n} + v$ and above, where at each new iteration the chain can visit one higher level. Based on that, a significant improvement resulted from Ramaswami's idea to compute R^2 by considering the embedded QBD on levels 2^k ($k = 0, 1, \dots$) and then determining R from a linear equation. This led to the quadratically convergent and numerically stable *logarithmic reduction algorithm* (LRA) for QBDs for computing the matrix G , published by Latouche and Ramaswami in 1993 [17] (also compare Ref. 1 or 18). The number of iterations necessary for attaining the same accuracy for G as in the linear algorithm with K steps is $\lfloor \log_2 K \rfloor$.

$G = A_2 + A_1G + A_0G^2$ is the “QBD-version” of the matrix equation appertaining to the $M/G/1$ type counterpart of the considered $GI/M/1$ type model. QBDs represent the bridge between both canonical types. Let C_k denote the block entries of the spatially homogeneous part in an $M/G/1$ type characteristic matrix of upper block Hessenberg form ($k \in \mathbb{N}_0$), such that $G = \sum_{k=0}^{\infty} C_k G^k$. As for QBDs, G (the *fundamental period matrix*) is the matrix of probabilities G_{ij} that, starting in (n, i) , the process eventually reaches level $\mathbf{n} - 1$ in state $(n - 1, j)$ avoiding levels below $\mathbf{n}$ in intermediate steps. Whereas R , in the $GI/M/1$ type case, neither is substochastic nor stochastic, G is stochastic and, equivalently, has a spectral radius equal to 1 provided that $C = \sum_{k=0}^{\infty} C_k$ is irreducible and the chain is recurrent [19,20]. Exploiting these properties, Bini and Meini [21] developed a quadratically convergent and numerical stable algorithm for the computation of G by extending a technique of successive state reduction—known as *cyclic reduction* or *even-odd reduction* in linear algebra [22]—to infinite block matrices of $M/G/1$ type (for a convincing description of the copiousness of this technique the reader

should consult Ref. 23). The algorithm is similar to the LRA when restricted to QBDs, and has been advanced subsequently in several steps [24–26]. Its significance for matrix-geometric methods lies in the fact that it can as well be utilized to compute R due to an important duality result of Ramaswami [27]. Let ${}_n P_{n;n+r}^{(k)}(t)$ denote the k -step probability matrix for transitions from level $\mathbf{n}$ to level $\mathbf{n} + \mathbf{r}$ in $(0, t]$ under taboo of levels $\leq \mathbf{n}$, and ${}_n P_{n-r;n}^{(k)}(t)$ the corresponding matrix regarding transitions from level $\mathbf{n}$ to level $\mathbf{n} - \mathbf{r}$ for the $M/G/1$ paradigm (under taboo of levels $\geq \mathbf{n}$, $n \geq r$ in the spatially homogeneous part). Then the following double transforms are defined for $|z| \leq 1$, $Re(s) \geq 0$: $R^{[r]}(z, s) = \sum_{k=0}^{\infty} \int_0^{\infty} z^k e^{-st} {}_n P_{n;n+r}^{(k)}(dt)$, $G^{[r]}(z, s) = \sum_{k=0}^{\infty} \int_0^{\infty} z^k e^{-st} {}_n P_{n-r;n}^{(k)}(dt)$. With $R^{[r]}(z, s) = [R(z, s)]^r$, $G^{[r]}(z, s) = [G(z, s)]^r$, and $R^{[1]}(z, s) = R(z, s)$, $G^{[1]}(z, s) = G(z, s)$, these transform expressions satisfy the nonlinear matrix equations $R(z, s) = z \sum_{k=0}^{\infty} C_k^*(s) [G(z, s)]^k$ [5,20,28]. The $A_k^*(s)$ and $C_k^*(s)$ are the respective Laplace–Stieltjes transforms of the kernel entries $A_k(t)$ and $C_k(t)$ that belong to the Markov renewal processes (MRPs) with interrenewal times equal to interarrival times in the $GI/M/1$ type model, and inter-service-completion times in the $M/G/1$ type model. $A_k(\infty)$ equals A_k in Equation (2), and $C_k(\infty) = C_k$ in its upper Hessenberg counterpart. Using these constructs, Ramaswami [27] proved the following theorem: Assume that $A = \sum_{k=0}^{\infty} A_k$ is irreducible, $\psi = (\psi_1, \dots, \psi_m)$ is its positive invariant vector, and Δ is the diagonal matrix with diagonal entries $\psi_1, \dots, \psi_m$. Then, setting $C_k^*(s) = \Delta^{-1} [A_k^*(s)]^T \Delta$, the characteristic matrix of the time reversed dual $M/G/1$ type MRP has block entries $C_k = C_k^*(0)$ and is related to the considered matrix of the $GI/M/1$ type MRP by

$$R(z, s) = \Delta^{-1} [G(z, s)]^T \Delta.$$

$C = \sum_{k=0}^{\infty} C_k$ is irreducible. $R = R(1, 0)$ and $G = G(1, 0)$ yield $R = \Delta^{-1} G^T \Delta$. Consequently, any algorithm for evaluating G , in particular those developed by Bini, Meini and colleagues, provide solutions for R (as well as moments) with same efficiency.

FURTHER READING

Neuts, giving prominence to the role of structure, promoted algorithmic probability as “the study of stochastic models with a genuine added concern for algorithmic feasibility” [5,29]. In Ref. 30 Neuts provides an important survey. Textbook introductions can be found, for example, in Nelson [14] and Kant [10]. In Ref. 31, by enlarging the state space and decomposing transitions from (n, i) to $(n + k, j)$ into sequences of single step transitions in the larger space, Ramaswami showed the generality of QBDs comprising $GI/M/1$ -type processes (same techniques apply to $M/G/1$ type systems). An overview on applications of QBDs to computer performance analysis is given in Ref. 32. In Ref. 33, parallel-server scheduling models are analyzed, and in Ref. 34, the behavior of a synchronization queue with Markovian arrival process is modeled as a finite state QBD. Systems with continuously varying levels can be related to QBDs, too, as shown by Ramaswami [35]. He established a connection by introducing a stochastic coupling of a Markov modulated fluid flow model (MMFF) with a queue of QBD characteristics and developed, on this basis, quadratically convergent algorithms similar to those mentioned in the previous section. Subsequently, much progress has been achieved with respect to the steady-state and transient behavior of a wide class of MMFF's as documented in a series of papers by Ahn and Ramaswami [36–39]. Efficient algorithms for the computation of busy period transform expressions are presented in Ref. 39. A concise survey on these results is given in Ref. 40. Additionally, first passage times in fluid models have been analyzed by Ramaswami [41] via QBD techniques. The first generalization of $GI/M/1$ type models to systems with continuously varying level, but, was introduced in 1989 by Sengupta [42], who considered a bivariate Markov process $\{(N_t, J_t) : t \geq 0\}$ whose level component can increase linearly or can have downward jump discontinuities; stationary distributions assume a matrix-exponential form in this case. In Ref. 43, Sengupta showed for the discrete time

process $\{(N_k, J_k) : k \in \mathbb{N}_0\}$ that the marginal steady-state distribution of N_k is discrete phase type. In Ref. 44, considering queues with (in case dependent) semi-Markov arrival and service processes, Sengupta obtained the matrix-exponential form for waiting times and proved that queue length distributions are matrix-geometric if arrival and service processes are independent. Generalizations of the $GI/M/1$ paradigm are handled in Ref. 45, where the level variable can take values in a tree structure, and in Ref. 46, where the phase variables are defined over a general measure space. In Ref. 47, Latouche considers invariant measures of matrix-geometric form. Multi-server retrial queues, modeled as continuous time $GI/M/1$ -type processes, were analyzed by Artalejo *et al.* [48]. An extensive survey on iterative methods for the computation of rate matrices is given in Ref. 49. The textbook [50] deals with numerical methods for the analysis of structured Markov chains as developed by Bini, Meini, and colleagues (compare also the first textbook on numerical evaluation of Markov chains published by Stewart [18]). In Ref. 51, a software package based on the above mentioned methods is provided. Recently, Bini *et al.* contributed careful comparisons between cyclic and logarithmic reduction [52].

MAXIMUM CLIQUE, MAXIMUM INDEPENDENT SET, AND GRAPH COLORING PROBLEMS

JEFF PATTILLO

Department of Mathematics, Texas A&M University, College Station, Texas

SERGIY BUTENKO

Department of Industrial and Systems Engineering, Texas A&M University, College Station, Texas

The maximum clique, maximum independent set, graph coloring, and minimum clique partitioning problems are classical problems in combinatorial optimization. Owing to their important role in several theoretical fields and applicability in a wide variety of practical settings, these problems have been extensively studied from different perspectives by mathematicians, computer scientists, operations researchers, engineers, biologists, and social scientists. This article surveys only a fraction of these research developments with the aim to provide a brief introduction to these problems for the operations research community. The reader is referred to surveys [1,2] for far more extensive information about each problem.

According to WordNet dictionary [3], clique is defined as “an exclusive circle of people with a common purpose.” Cliques, as described in the dictionary definition, represent a natural object of interest for social and behavioral sciences. Thus, it is not surprising that the first mentioning of this term in graph-theoretic context is attributed to researchers in social network analysis: in their 1949 paper [4], Luce and Perry used complete subgraphs to model social cliques, which are defined as groups of people that know (are friends of) all other people in the group. It should be noted that the complete subgraphs had been studied by mathematicians even before the term *clique* was introduced to graph theory.

Graph coloring problems have been around even longer, dating back to the

famous four-color conjecture first attacked in the nineteenth century [5,6], stating that regions of any simple planar map can be colored with four colors so that any two adjacent regions have different colors. The proof of this seemingly simple statement required the efforts of several generations of mathematicians and involvement of a computer [7,8].

Clique-like structures frequently arise in many other applications, where one is interested in detecting large groups of elements that are all closely related to each other in some sense. Depending on the application of interest, such structures are often referred to as *clusters*, *modules*, *complexes*, or *cohesive subgroups*. If the elements in the application of interest are represented as vertices (nodes) and the relationships between the elements are represented as edges (links, arcs), then clusters can be naturally modeled as cliques in this graph-theoretic representation. The specific application areas of the maximum clique and the graph coloring problems include information retrieval, signal transmission analysis, classification theory, economics, scheduling, experimental design, and computer vision [1,9–14]. The reader is referred to Butenko and Wilhelm [15] for a survey of applications of clique detection models in biochemistry and genomics. Applications of cliques and coloring in telecommunications are discussed in Balasundaram and Butenko [16].

In this article, we seek to give an introduction to these problems, their basic properties, as well as a brief summary of the most popular methods of solving the problems and the capabilities and limitations of these methods. We also describe some results concerning the maximum clique and the graph coloring problems in uniform random graphs (See also ***Network Theory: Concepts and Applications, Domination Problems, Clique Relaxations***).

DEFINITIONS AND NOTATIONS

Given a simple undirected graph $G = (V, E)$, where $V = \{1, \dots, n\}$ is the vertex set and $E \subseteq V \times V$ is its edge set, we denote by $G(S) = (S, E \cap S \times S)$, the subgraph induced by a subset of vertices S , and we use the notation $\bar{G}$ to represent the complement graph, that is $\bar{G} = (V, \bar{E})$ where $\bar{E} = \{(i, j) | i, j \in V, i \neq j \text{ and } (i, j) \notin E\}$. Vertices i and j are called *adjacent* if $(i, j) \in E$. The neighborhood $N(i)$ of a vertex i is the set of vertices adjacent to i , $N(i) = \{j \in V : (i, j) \in E\}$. By A_G we denote the *adjacency matrix* of G , which is an $n \times n$ matrix $A_G = [a_{ij}]_{i,j=1}^n$ such that $a_{ij} = 1$ if $(i, j) \in E$ and $a_{ij} = 0$ otherwise. The degree $\deg(i)$ of i in G is the size $|N(i)|$ of the neighborhood of i in G . We will denote by $\delta(G)$ and $\Delta(G)$ the smallest and the largest degree of a vertex in G , respectively.

A graph $G = (V, E)$ is called *complete* if all its vertices are adjacent, that is, if $\forall i, j \in V, i \neq j$, we have $(i, j) \in E$. By definition, a *clique* C is a subset of vertices such that $G(C)$ is complete. An *independent set* in G is a subset of vertices I such that the induced subgraph $G(I)$ is edgeless. A clique (independent set) is called *maximal* if it is not a subset of a larger clique (independent set) in G , and it is called *maximum* if there is no larger clique (independent set) in the graph. Given a simple undirected graph G , the *maximum clique problem* (*maximum independent set problem*) asks for a maximum clique (independent set) in G . The *clique number*, which is traditionally denoted as $\omega(G)$, is the number of vertices in the largest clique in G . The independence number $\alpha(G)$ is defined analogously. It is easy to see that C is a clique in G if and only if C is an independent set in $\bar{G}$; hence, $\omega(G) = \alpha(\bar{G})$. Owing to this close relation between the two concepts, we will use the notions of cliques and independent sets interchangeably in this article, since all the facts stated for a clique in G are true for an independent set in $\bar{G}$, and vice versa.

A *proper k -coloring* of the vertices of G is an assignment of colors (e.g., $\{1, 2, \dots, k\}$) to the vertices of G so that no two adjacent vertices get the same color. A vertex k -coloring can also be thought of as a mapping $f : V \rightarrow \{1, 2, \dots, k\}$ such that $f(v_i) \neq f(v_j)$ if

$(v_i, v_j) \in E$. A graph G is called *k -colorable* if there exists a proper k -coloring of its vertices. The *graph coloring problem* is to find a proper coloring of its vertices with the smallest possible number of colors. The *chromatic number* $\chi(G)$ of G is the smallest integer k for which G is k -colorable.

A k -coloring partitions V into k different *color classes*, where each member of the class has the same color. To have the same color, the members of each class must be pairwise nonadjacent, which by definition makes them an independent set. Similarly, one can define a *k -clique partitioning* of G , which is a partitioning of the set of vertices of G into k disjoint subsets $C_1, \dots, C_k$, each of which is a clique. The *minimum clique partitioning problem* asks for a k -clique partitioning of G using the smallest possible number k of cliques, which is denoted by $\bar{\chi}(G)$ and is called the *clique partitioning number*. Note that a proper k -coloring of G is a k -clique partitioning of $\bar{G}$, thus, $\chi(\bar{G}) = \bar{\chi}(G)$.

The maximum clique, maximum independent set, vertex coloring, and minimum clique partitioning problems are all known to be NP-hard [17]. Moreover, these problems are known to be hard to approximate. Arora *et al.* [18,19] showed that the maximum clique size cannot be approximated within a factor of n^ϵ for any $\epsilon > 0$ unless $P = NP$. Similarly, the graph coloring problem is not approximable within $n^{1-\epsilon}$ for any $\epsilon > 0$ [20].

MATHEMATICAL PROGRAMMING FORMULATIONS

The Maximum Clique Problem

The maximum clique problem can be formulated as the following integer program:

$$\begin{aligned} \max \quad & \sum_{i=1}^n x_i \\ \text{s.t.} \quad & x_i + x_j \leq 1, \quad \forall (i, j) \in \bar{E} \\ & x_i \in \{0, 1\}, \quad i = 1, \dots, n. \end{aligned} \quad (1)$$

In this *edge* formulation any feasible solution x defines a clique C in G as follows: $C = \{i \in V : x_i = 1\}$. The linear relaxation of this formulation is significant as well. Nemhauser

and Trotter [21] found that if a variable x_i in any optimal solution to the linear relaxation had the value 1, then $x_i = 1$ in at least one optimal solution to the above formulation. When some such variable $x_i = 1$, this clearly helps cut down the search space for an optimal clique.

Shor [22] modified the edge formulation to obtain an equivalent nonlinear problem:

$$\begin{aligned} \max \quad & \sum_{i=1}^n x_i \\ \text{s.t.} \quad & x_i x_j = 0, \quad \forall (i, j) \in \bar{E} \\ & x_i^2 - x_i = 0, \quad i = 1, \dots, n. \end{aligned} \quad (2)$$

He used this formulation to obtain dual estimates of good quality.

Motzkin and Straus [23] related $\omega(G)$ to the global optimal value of a certain quadratic function over the standard simplex. Before we state this classical formulation, some additional notations are in order. For a set of vertices C we use the notation x^C to denote the *characteristic vector* of C , which is a vector that satisfies $x_i^C = 1/|C|$ if $i \in C$ and $x_i^C = 0$, otherwise, for $i \in \{1, \dots, n\}$. By S we will denote the standard simplex in $\mathbb{R}^n$:

$$S = \left\{ x \in \mathbb{R}^n : \sum_{i=1}^n x_i = 1, x_i \geq 0, i = 1, \dots, n \right\}.$$

Let A_G be the adjacency matrix of a graph G , and for $x \in \mathbb{R}^n$ let $g(x) = x^T A_G x$. Then the global optimal solution x^* to $\max_{x \in S} g(x)$ is related to the clique number by the formula

$$\omega(G) = \frac{1}{1 - g(x^*)}.$$

The following generalization of the Motzkin–Straus theorem was introduced by Bomze [24] to guarantee a one-to-one correspondence between maximal cliques and local maximizers of the quadratic program. Let $f(x) = x^T A_G x + \frac{1}{2} x^T x$.

Theorem 1. *Let C be a subset of vertices of a graph G , and let x^C be its characteristic vector. Then the following statements hold:*

- *C is a maximum clique of G if and only if x^S is a global maximizer of the function f over the simplex S . In this case, $\omega(G) = \frac{1}{2(1-f(x^C))}$.*
- *C is a maximal clique of G if and only if x^C is a local maximizer of f over S .*
- *All local (and hence global) maximizers x of g over S are strict, and of the form $x = x^C$ for some $C \subseteq V$.*

The maximum independent set problem can be equivalently formulated using the following mathematical programs over the unit hypercube in $\mathbb{R}^n$ [25,26]:

$$\alpha(G) = \max_{x \in [0,1]^n} \sum_{i \in V} x_i - \sum_{(i,j) \in E} x_i x_j. \quad (3)$$

$$\alpha(G) = \max_{x \in [0,1]^n} \sum_{i \in V} x_i \prod_{j \in N(i)} (1 - x_j). \quad (4)$$

$$\alpha(G) = \max_{x \in [0,1]^n} \sum_{i \in V} \frac{x_i}{1 + \sum_{j \in N(i)} x_j}. \quad (5)$$

In each of these formulations, the feasible region can be replaced with $\{0, 1\}^n$ without changing the optimal objective value. Several other similar formulations can be found in Harant [27].

Recently, Martins [28] proposed discretized formulations for the maximum clique problem and reported tighter upper bounds based on linear programming relaxations than those for the known formulations on many benchmark graphs.

Formulations of the Graph Coloring Problem

The following is perhaps the most straightforward integer programming formulation of the graph coloring problem. Let r be an upper bound on the chromatic number of G . We have:

$$\begin{aligned} \chi(G) = \min \quad & \sum_{k=1}^r y_k \\ \text{s.t.} \quad & \sum_{k=1}^r x_{ik} = 1, \quad \forall i \in V \end{aligned}$$

$$\begin{aligned}
x_{ik} + x_{jk} &\leq 1, \quad \forall (i, j) \in E, \\
k &= 1, \dots, r \\
y_k &\geq x_{ik}, \quad \forall i \in V, \quad k = 1, \dots, r \\
y_k, x_{ik} &\in \{0, 1\} \quad \forall i \in V, \\
k &= 1, \dots, r.
\end{aligned} \tag{6}$$

In this formulation, the variable y_k indicates whether the k th from the r available colors is used, and $x_{ik} = 1$ if and only if the k th color is used for vertex i . The first set of constraints ensures that exactly one color is used for each vertex, and the remaining two sets of constraints guarantee that the coloring is proper and that all used colors are counted. Thus, any feasible solution induces a proper coloring by assigning each vertex i the unique color k for which $x_{ik} = 1$. The optimal objective function value gives the chromatic number of the graph. Note that the formulation remains valid if the variables $y_k, k = 1, \dots, r$ are not required to be integers.

The following integer programming formulation has the optimal objective equal to zero if and only if the graph has a proper r -coloring:

$$\begin{aligned}
\min \quad & \sum_{k=1}^r \sum_{(i,j) \in E} x_{ik} x_{jk} \\
\text{s.t.} \quad & \sum_{k=1}^r x_{jk} = 1, \quad j = 1, \dots, n \\
& x_{jk} \in \{0, 1\}, \quad j = 1, \dots, n, \quad k = 1, \dots, r.
\end{aligned} \tag{7}$$

This formulation has a quadratic objective function, but its constraint set is much simpler than in the previous formulation.

Let $\mathcal{I}$ be the set of all maximal by inclusion independent sets of $G = (V, E)$. For each $I \in \mathcal{I}$, let a binary variable x_I be such that $x_I = 1$, if and only if all vertices in I use the same color in a proper coloring of G . Then we have the following *set covering* formulation of the graph coloring problem [29]:

$$\chi(G) = \min \sum_{I \in \mathcal{I}} x_I$$

$$\begin{aligned}
\text{s.t.} \quad & \sum_{I: i \in I} x_I \geq 1 \quad \forall i \in V \\
& x_I \in \{0, 1\}, \quad I \in \mathcal{I}.
\end{aligned} \tag{8}$$

BOUNDS

Since the number of vertices in any color class defined by a proper coloring of G cannot exceed $\alpha(G)$, we obtain the following inequality:

$$\chi(G) \geq \frac{|V|}{\alpha(G)}. \tag{9}$$

The Caro–Wei bound on the independence number is expressed in terms of vertex degrees as follows [30,31]:

$$\alpha(G) \geq \sum_{i \in V} \frac{1}{\deg(i) + 1}. \tag{10}$$

This bound is sharp if and only if each connected component of G is a clique. Note that the Caro–Wei bound follows from formulation (5) by setting all variables to 1.

In 1967, Wilf [32] showed that

$$\omega(G) \leq \rho(A_G) + 1, \tag{11}$$

where $\rho(A_G)$ is the spectral radius of the adjacency matrix of G (the largest eigenvalue of A_G).

Amin and Hakimi [33] proved that

$$\omega(G) \leq N_{-1} + 1 < n - N_0 + 1, \tag{12}$$

where N_{-1} is the number of eigenvalues of A_G that do not exceed -1 , and N_0 is the number of zero eigenvalues. This bound is sharp if G is a complete multipartite graph.

Applying a greedy coloring yields a simple upper bound on the chromatic number:

$$\chi(G) \leq \Delta(G) + 1. \tag{13}$$

Brook’s theorem [34] slightly improves this bound for connected graphs: for a connected, simple graph G that is not a complete graph or an odd cycle, we have

$$\chi(G) \leq \Delta(G). \tag{14}$$

Szekeres and Wilf [35] generalized the bound 13 by proving that for any function $\lambda(G)$ satisfying two properties, (i) $G' \subset G \Rightarrow \lambda(G') \leq \lambda(G)$ and (ii) $\lambda(G) \geq \delta(G)$, we have

$$\chi(G) \leq \lambda(G) + 1.$$

Reed [36] conjectured that for every graph G ,

$$\chi(G) \leq \frac{1}{2}(\Delta(G) + \omega(G)) + 1. \quad (15)$$

The clique number $\omega(G)$ and chromatic number $\chi(G)$ satisfy the inequality $\omega(G) \leq \chi(G)$, since every vertex in the largest clique is adjacent to every other vertex in this clique, and thus requires a different color. What is remarkable is that there exists a polynomially computable graph function $\vartheta(G)$, known as the Lovász ϑ -function [37], that always satisfies the *sandwich theorem* [38]:

$$\omega(G) \leq \vartheta(\overline{G}) \leq \chi(G) \quad (16)$$

Hence, $\vartheta(\overline{G})$ provides a polynomially computable upper bound on $\omega(G)$ and lower bound on $\chi(G)$.

A graph G , such that for any subset of vertices $S \subseteq V$ the corresponding induced subgraph has equal clique and chromatic numbers, $\omega(G(S)) = \chi(G(S))$, is called *perfect*. Recently, Chudnovsky *et al.* [39] proved the strong perfect graph theorem (first conjectured by Claude Berge in 1960) stating that a graph is perfect if and only if it contains no odd hole (that is, a chordless cycle of length at least four) and no odd antihole (a complement of a hole). Hence, checking whether a graph G is perfect can be done in polynomial time. On the other hand, Busygin and Pasechnik [40] proved that recognizing whether $\chi(G) - \omega(G) = 0$ is *NP*-hard, implying that any polynomially computable parameter that lies between $\omega(G)$ and $\chi(G)$ will provide the “provably best” upper bound for the independence number in the sense that no other polynomially computable bound can improve this bound whenever it can be improved. In particular, the Lovász theta is one such bound.

COMPUTING CLIQUES AND COLORINGS

Exact Solutions

The early algorithms for the maximum clique problem were motivated by various applications and, because of the nature of the considered applications, aimed to enumerate all maximal cliques in the graph rather than just finding a single maximum clique. In 1957, Harary and Ross [41] published the first algorithm for enumerating all maximal cliques in a graph, which was motivated by an application in sociometry. Their method first reduces the problem on general graphs to a special case with graphs having at most three maximal cliques, and then solves the problem for this special case. Many other algorithms for enumerating all maximal cliques followed [42–45].

The progress in computing technologies in the 1960s motivated the development of many new enumerative algorithms. Bron and Kerbosch [46] proposed a backtracking method that requires only polynomial storage space and excludes the possibility of computing the same clique twice. Various versions of this algorithm are still used in many different applications, in particular, in computational biology, where it was found very effective for problems related to matching three-dimensional molecular structures [47]. Tomita *et al.* [48] developed a modification of this approach, which has the time complexity of $O(3^{n/3})$. This complexity is cannot be improved for enumerative algorithms, since there are graphs with $3^{n/3}$ maximal cliques [49]. More recently, Tomita *et al.* [50] presented a depth-first search algorithm for generating all maximal cliques of an undirected graph, which uses the same pruning rules as the Bron–Kerbosch algorithm, and also has $O(3^{n/3})$ worst-case time complexity. They report encouraging results of computational experiments.

Many exact algorithms for the maximum clique and related problems have been proposed in the literature, most of which can be viewed as variations of the branch-and-bound technique. Some of the algorithms were designed with worst-case time complexity in mind, while others emphasize the practical performance. In 1977, Tarjan

and Trojanowski [51] proposed a recursive algorithm for the maximum independent set problem with the time complexity of $O(2^{n/3})$. Later, Robson [52] improved this result to obtain the time complexity of $O(2^{0.276n})$. In 2001, Robson [53] further brought down the best-known worst-case complexity to $O(2^{n/4})$.

As for more practical algorithms, Balas and Yu [11] used an interesting implementation of the implicit enumeration, capable of computing maximum cliques in graphs with up to 400 vertices and 30,000 edges. Carraghan and Pardalos [54] proposed an alternative, simpler approach examining vertices in the order corresponding to the nondecreasing order of their degrees within the implicit enumeration framework. This method proved to be extremely effective, especially for sparse graphs and was selected as a benchmark for comparing different algorithms in The Second DIMACS Implementation Challenge [55]. Östergård [56] proposed a branch-and-bound algorithm that employs a vertex ordering based on approximate coloring. This algorithm showed an excellent performance on random graphs and DIMACS benchmark instances and is considered the state-of-the-art general-purpose exact algorithm for the maximum clique problem by many researchers. Tomita and Kameda [57] used similar ideas in their branch-and-bound algorithm, which also uses approximate coloring along with an appropriate sorting of vertices. They report superior computational results on graphs with up to 15,000 vertices, including instances arising in image processing, design of quantum circuits, and bioinformatics.

As we have seen in the previous section, the maximum clique and graph coloring problems can be formulated as integer or continuous nonconvex programs. Modern integer programming solvers typically combine branch-and-bound strategies with cutting-plane methods, efficient preprocessing schemes, including fast heuristics, and sophisticated decomposition techniques in order to find an exact solution, and may be quite effective even with their default settings when used with an appropriate integer programming formulation. However, the experience shows

that developing specialized strategies based on a detailed polyhedral study of the specific problem helps to speed up the computations and tackle larger problem instances. Several attempts of using algorithms based on the polyhedral properties of the maximum clique problem have been reported in the literature. For example, Bourjolly *et al.* [58] propose a column generation algorithm for the maximum stable set problem, and Rossi and Smriglio [59] reports encouraging computational results with a branch-and-cut algorithm for the same problem. While these approaches show some promise and may still be improved in the future, at the moment they are, generally speaking, outperformed by the above-mentioned branch-and-bound strategies in practice.

The exact algorithms for the graph coloring follow the same general line of development as for the maximum clique problem. Brown [60] proposed a branch-and-bound algorithm that uses a sequential greedy coloring heuristic (SCGH) described in the next section. Several improvements were suggested later [55,61,62]. Mehrotra and Trick [29] developed a column generation approach for graph coloring. Herrmann and Hertz [63] attempt to compute the chromatic number of a graph G by first determining a critical subgraph, which is the smallest induced subgraph of G that has the same chromatic number. They report very encouraging computational results. Lucet *et al.* [64] proposed yet another algorithm for the graph coloring problem based exactly on a linear decomposition of the graph. This method is exponential with respect to the linear width of the input graph, but only linear with respect to its number of vertices. The method was used to successfully solve some of the problem instances for the first time.

Approximation Algorithms and Heuristics

Owing to the inapproximability of the maximum clique and graph coloring problems mentioned above, the approximation algorithms for these problems, normally, have nonconstant performance ratio and are of mostly theoretical value. For example,

a greedy algorithm that builds a maximal independent set by recursively adding a minimum degree vertex and removing its neighbors has an approximation ratio of $(\Delta(G) + 2)/3$ [65]. Johnson [66] presented an algorithm for graph coloring with a performance guarantee of $O(n \log n)$.

Heuristics for the maximum clique and graph coloring problems usually have little theoretical justification or performance bounds. Thus evaluations of which heuristics tend to work best in which situations are mostly based on experimentation. The heuristics listed below are among the most popular and successful.

Greedy Construction Heuristics. Greedy heuristics for the maximum clique problem typically work in one of two ways: either adding in vertices into a partial clique until no more can be inserted or deleting vertices from a set of vertices that is not a clique until it induces a complete subgraph. The rule governing which vertex to add or delete next is usually based upon simple local information, such as the degree of the vertex. Heuristics such as this tend to run extremely fast. For examples of greedy heuristics, see Johnson [67], Kopf and Ruhe [68], and Tomita *et al.* [69].

The most commonly implemented greedy heuristic for the coloring problem is called the *sequential greedy coloring heuristic (SGCH)*. The first step of this algorithm is to specify some vertex ordering. After that each vertex is colored in the specified order in a greedy method, using the smallest feasible color. There will always be an ordering that will lead to an optimal coloring. To see this, suppose the color classes from an optimal coloring are $\{S_1, \dots, S_k\}$. If SGCH is applied to an ordering where all of S_1 is colored, then all of S_2 , then all of S_3 , and so on, it is easy to see that, while the same exact coloring may not be obtained, it will certainly not use more than k colors. Because of this fact, heuristics with greedy coloring tend to concentrate heavily on the order in which the vertices are colored.

Ordering schemes based on vertex degrees, such as largest first [70], smallest last [71], and dynamic ordering schemes that

do not preorder vertices [61, 72] have all been well studied. For research into how one can move gradually from an initial ordering to an optimal ordering, see Biggs [73], Chams *et al.* [74], and White [75].

Local Search Heuristics. The definition of the neighborhood is a critical element of a local search algorithm. The most common neighborhoods for the maximum clique and the graph coloring problems are the so-called *exchange neighborhoods*. An exchange neighborhood for the maximum clique problem is defined as follows: given a clique representing the current solution, its neighbors are obtained by removing one or more vertices from the clique and adding at least as many new vertices to the clique whenever possible. For graph coloring, the exchange is typically performed between different color classes. Namely, given a proper coloring, its neighbors are obtained by moving a certain number of vertices from one color class to another in an attempt to eventually reduce some of the color classes to empty set, thus obtaining a better coloring. Oftentimes, exchanges resulting in infeasible solutions are allowed with a penalty added to the objective for the infeasibility. This is done to diversify the search to increase the chances of identifying a high quality solution.

In Culberson [76], an alternative iterative improvement heuristic for the coloring problem is proposed. The paper notes that if you take a coloring $\{S_1, \dots, S_r\}$, where the S_i 's are the color classes, then coloring an ordering of the form $(S_{i_1}, \dots, S_{i_r})$ by a greedy heuristic, so that each color class is colored entirely before the next class, can only improve upon the previous coloring. This observation is independent of the ordering of the vertices within each class, as well as the order in which the classes appear, so in Culberson [76] various ordering schemes of the classes are explored. Typically a mixture of the schemes is best because it allows the algorithm to search a "larger" neighborhood of potential solutions.

While traditional local search methods are typically capable of improving on the solutions generated by construction heuristics, they are known for their tendency

to often getting trapped in local optima of rather poor quality. Several strategies commonly used to overcome this drawback are briefly reviewed in the next section. Various other heuristics can be found in Johnson and Trick [55] and Caramia and Dell’Olmo [77].

Metaheuristics. While many metaheuristic strategies, such as neural networks, genetic algorithms, and evolutionary computing have been applied to the maximum clique and graph coloring problems, few offer very good results [1]. Both problems do, however, surrender good results to the same two metaheuristic methods: simulated annealing and tabu search.

For different implementations of simulated annealing to solve the maximum clique problem, see Aarts and Korst [78] and Homer and Peinado [79]. It is interesting to note that it has been shown in Jerrum [80] that, theoretically, simulated annealing should perform poorly for the clique problem, but the results in Homer and Peinado [79] conclude just the opposite. Simulated annealing actually outperforms most other heuristics on the clique problem in experiments in that paper. Pure versions of simulated annealing for the coloring problem, along with implementations where it is combined with greedy heuristics, exist in Chams *et al.* [74] and Johnson *et al.* [81]. It seems to outperform most greedy heuristics both in time and quality of the solution on random graphs of up to 1000 vertices.

The implementations of tabu search that have performed well for the maximum clique problem can be found in Battiti and Protasi [82], Gendreau *et al.* [83], and Soriano and Gendreau [84,85]. For implementations of tabu search for the graph coloring problem, see de Werra [86], Hertz [87], and Hertz and de Werra [88]. For results comparing not only simulated annealing and tabu search but also greedy heuristics on random graphs of up to 500 vertices and varying densities, see Klimowicz and Kubale [89].

Heuristics based on Continuous Optimization. The Motzkin–Straus formulation yields another potential way of solving the max

clique problem, shifting it from a discrete to a continuous setting. Gibbons *et al.* [90] relaxed the Motzkin–Straus formulation to where it became a problem of optimizing a quadratic over a sphere, which is solvable in polynomial time. The drawback is that solutions may become infeasible for the original problem and hence have to be rounded. Their algorithm performed well on DIMACS benchmark graphs, as recorded in Gibbons *et al.* [90].

Others have taken advantage of the fact that the Motzkin–Straus formulation happens to be a *replicator equation*. A replicator equation, appropriately named because it behaves like the fitness of a population as it replicates, is an equation that as each new solution is plugged in recursively, always increases. With enough starts in random locations, one hopes that recursively plugging in solutions to the replicator equation will end in discovering the global optimum. For a discussion on algorithms to take advantage of the Motzkin–Straus formulation as a replicator equation, including how to remove the need for iteration in the procedure and empirical analysis, see Bomze *et al.* [91] and Bomze and Stix [92]. Results on benchmark graphs are reported in Johnson and Trick [55].

Burer *et al.* [93] studied rank-one and rank-two relaxations of the Lovász semidefinite program [94] and obtained two continuous formulations for the maximum independent set problem. They used these formulations to develop new heuristics for finding large independent sets. Several other heuristics for the maximum independent set problem based on continuous optimization techniques have been proposed in the literature [25,95–97].

As for the graph coloring problem, Karger *et al.* [98] used semidefinite programming to approximate graph coloring. More recently, Dukanovic and Rendl [99] used information provided by near-optimal solutions of a semidefinite programming formulation for the Lovász ϑ -function to generate heuristic solutions for the graph coloring problem. On the basis of the results of numerical experiments, they suggest that this approach could be useful for coloring medium-sized instances.

CLIQUE AND CHROMATIC NUMBERS IN UNIFORM RANDOM GRAPHS

In this section we provide some results concerning the asymptotic behavior of clique and chromatic numbers in *random graphs*. Erdős and Rényi [100–102] founded the random graph theory by introducing several models of *uniform* random graphs. Two of the most popular such models are $G(n, m)$ and $\mathcal{G}(n, p)$ [103], the first of which assigns the same probability to all graphs with n vertices and m edges, while in the second model each pair of vertices is connected by an edge randomly and independently with probability p .

Studying the asymptotic behavior of various graph properties may provide reasonable theoretical estimates of graph invariants for massive graph instances that cannot be tackled by a computer. We say that *almost every* (a.e.) graph has property Q , or the property Q holds *asymptotically almost surely* (a.a.s.), if the probability that a random graph on n vertices has property Q tends to 1 as $n \rightarrow \infty$. Erdős and Rényi observed that many graph properties either hold or do not hold for almost every graph.

Clique Number

Assume that $0 < p < 1$ is fixed. Then instead of the sequence of spaces $\{\mathcal{G}(n, p), n \geq 1\}$ one can work with the single probability space $\mathcal{G}(\mathbf{N}, p)$ containing graphs on $\mathbf{N}$ with the edges chosen independently with probability p . For a graph $G \in \mathcal{G}(\mathbf{N}, p)$ we denote by G_n the subgraph of G induced by the first n vertices $\{1, 2, \dots, n\}$. Then the sequence $\omega(G_n)$ appears to be almost completely determined for a.e. $G \in \mathcal{G}(\mathbf{N}, p)$.

Bollobás and Erdős [104] proved that if $p = p(n)$ satisfies $n^{-\epsilon} < p \leq c$, for every ϵ and some $c < 1$, then there exists a function $cl : \mathbf{N} \rightarrow \mathbf{N}$ such that a.a.s.

$$cl(n) \leq \omega(G_n) \leq cl(n) + 1,$$

that is, the clique number is asymptotically distributed on at most two values. The sequence $cl(n)$ appears to be close

to $l_0(n) = 2 \log_{1/p} n + O(\log \log n)$: for a.e. $G \in \mathcal{G}(\mathbf{N}, p)$ if n is large enough then

$$\begin{aligned} |l_0(n) - 2 \log \log n / \log n| &\leq \omega(G_n) \\ &\leq \lfloor l_0(n) + 2 \log \log n / \log n \rfloor \end{aligned}$$

and

$$\begin{aligned} |\omega(G_n) - 2 \log_{1/p} n + 2 \log_{1/p} \log_{1/p} n \\ - 2 \log_{1/p}(e/2) - 1| &< \frac{3}{2}. \end{aligned}$$

Frieze [105] and Janson *et al.* [106] extended these results by showing that for $\epsilon > 0$ there exists a constant c_ϵ , such that for $\frac{c_\epsilon}{n} \leq p(n) \leq \log^{-2} n$ a.a.s.

$$\begin{aligned} |2 \log_{1/p} n - 2 \log_{1/p} \log_{1/p} n + 2 \log_{1/p}(e/2) \\ + 1 - \epsilon/p| &\leq \omega(G_n) \leq |2 \log_{1/p} n \\ - 2 \log_{1/p} \log_{1/p} n \\ + 2 \log_{1/p}(e/2) + 1 + \epsilon/p|. \end{aligned}$$

Chromatic Number

The problem of coloring random graphs has been studied by several researchers Bollobás [107], Alon and Krivelevich [108], Grimmett and McDiarmid [109], Sós and Straus [110], and Łuczak [111]. Łuczak [111] improved the previous results about the concentration of $\chi(G(n, p))$, proving that for every sequence $p = p(n)$ such that $p \leq n^{-6/7}$ there is a function $ch(n)$ such that a.a.s.

$$ch(n) \leq \chi(G(n, p)) \leq ch(n) + 1.$$

Alon and Krivelevich [108] have shown that for any positive constant γ the chromatic number of a uniform random graph $G(n, p)$, where $p = n^{\frac{1}{2}-\gamma}$, is a.a.s. distributed among two consecutive values. Moreover, a proper choice of $p(n)$ may result in a one-point distribution. The function $ch(n)$ is difficult to find in general, however, it can be characterized in some cases. In particular, Janson *et al.* [106] proved that there exists a constant c_0 such that for any $p = p(n)$ satisfying $\frac{c_0}{n} \leq p \leq \log^{-7} n$ a.a.s.

$$\frac{np}{2 \log np - 2 \log \log np + 1} \leq \chi(G(n, p))$$

$$\leq \frac{np}{2 \log np - 40 \log \log np}.$$

If p is constant, we have the following estimate:

$$\chi(G(n, p)) = \frac{n}{2 \log_b n - 2 \log_b \log_b n + O_c(1)},$$

where $b = 1/(1 - p)$.

The *maximum flow problem* seeks the maximum possible flow in a capacitated network from a specified source node to a specified sink node without exceeding the capacity of any arc while conserving the flow at the intermediate nodes. The dual of this problem is the *minimum cut problem*, which seeks a set of arcs with the smallest total capacity whose removal separates the source node and the sink node.

The maximum flow and minimum cut problems arise in a variety of application settings as diverse as manufacturing, communication systems, distribution planning, and scheduling. Moreover, we come across these problems as subproblems in the solution of more difficult network optimization problems. The maximum flow problem directly occurs in problems such as machine scheduling, the assignment of computer modules to computer processors, the rounding of census data to retain the confidentiality of individual households, and tanker scheduling. In this article, we study the maximum flow and minimum cut problems by introducing the underlying theory and algorithms. Ahuja *et al.* [1] contains a wealth of additional material that expands this discussion.

We provide the representative selection problem as an example of a maximum flow problem. Consider a town that has r residents

$R_1, R_2, \dots, R_r$; q clubs $C_1, C_2, \dots, C_q$; and p political parties $P_1, P_2, \dots, P_p$. Each resident is a member of at least one club and can belong to exactly one political party. Each club must nominate one of its members to represent it in the town's governing council so that the number of council members belonging to the political party P_k is at most u_k . Is it possible to find such a "balanced" council?

We consider a problem with $r = 7, q = 4, p = 3$ and formulate it as a maximum flow problem in Fig. 1. The network also contains a source node s and a sink node t . It contains an arc (s, C_i) for each node C_i denoting a club, an arc (C_i, R_j) whenever the resident R_j is a member of the club C_i , and an arc (R_j, P_k) if the resident R_j belongs to the political party P_k . Finally, we add an arc (P_k, t) for each $k = 1, 2, 3$ of capacity u_k ; all other arcs have unit capacity. The number over an arc represents the arc capacity.

We next find a maximum flow value in this network. If the maximum flow value equals q , then the town has a balanced council; otherwise, it does not. This is because any flow of value q in the network corresponds to a balanced council.

LINEAR PROGRAMMING FORMULATION

Let $G = (N, A)$ be a *directed network* defined by a set N of n nodes and a set A of m directed arcs. We refer to nodes i and j as *end points* of arc (i, j) . A *directed path* $i_1 \rightarrow i_2 \rightarrow \dots \rightarrow i_k$ is a set of arcs $(i_1, i_2), (i_2, i_3), \dots, (i_{k-1}, i_k)$. Each arc (i, j) has an associated *capacity* u_{ij} denoting the maximum possible amount of flow on this arc. We assume that each arc capacity u_{ij} is an integer, and let $U = \max\{u_{ij} : (i, j) \in A\}$. The network has two distinguished nodes, a *source node* s and a *sink node* t .

The maximum flow problem is to find the maximum flow from the source node s to the sink node t that satisfies the arc capacities and mass balance constraints at all nodes. We can state the problem formally as follows:

Figure 1. System of distinct representatives.

Maximize v

subject to

$$\sum_{\{j:(i,j) \in A\}} x_{ij} - \sum_{\{j:(j,i) \in A\}} x_{ji} = \begin{cases} v & \text{for } i = s \\ 0 & \text{for } i \neq s \text{ or } t \\ -v & \text{for } i = t, \end{cases} \quad (1a)$$

$$0 \leq x_{ij} \leq u_{ij} \text{ for all } (i,j) \in A. \quad (1b)$$

We refer to a vector $x = \{x_{ij} : (i,j) \in A\}$ satisfying Equations (1a) and (1b) as a *flow*, and the corresponding value of the scalar variable v as the *value* of the flow. We refer to the constraints (1a) as the *mass balance constraints*, and we refer to the constraints (1b) as the *flow bound constraints*.

The maximum flow problem is a special type of minimum cost flow problem and can be formulated as a minimum cost flow problem by adding an arc from node t to s , and setting the capacity of this arc to infinity (if it does not exist).

In examining the maximum flow problem, we impose the following assumptions.

Assumption 1. Whenever the network contains $\text{arc}(i,j)$, then it also contains $\text{arc}(j,i)$.

This assumption is satisfied by adding the missing arcs with zero capacities.

Assumption 2. The network is directed.

If the network contains an undirected arc (i,j) with capacity u_{ij} , it means that this arc permits flow from node i to node j and also from node j to node i . The total flow (from node i to node j , plus from node j to node i) has an upper bound u_{ij} . It can be shown that the undirected problem can be reduced to the directed problem with comparable size and capacity values [2].

Assumption 3. The lower bounds on the arc flows are zero.

Sometimes the flow vector x might be required to satisfy lower bound constraints imposed upon the arc flows; that is, for each arc $(i,j) \in A$, we impose the condition $x_{ij} \geq l_{ij}$. Whereas the maximum flow problem with zero lower bounds always has a feasible solution (since the zero flow is feasible), the problem with nonnegative lower bounds could be infeasible (Fig. 2). This problem does not have a feasible solution because arc $(s, 2)$ must carry at least five units of flow into node 2, and arc $(2, t)$ can take out at most

Figure 2. A maximum flow problem with no feasible solution.

four units of flow; therefore, we can never satisfy the mass balance constraint of node 2.

Any maximum flow algorithm for problems with nonnegative lower bounds has two phases: (i) to determine whether the problem is feasible or not, and (ii) if feasible, to establish a maximum flow. It can be shown that each phase essentially reduces to solving a maximum flow problem with zero lower bounds [2].

Assumption 4. *There is a single source and a single sink.*

If the problem is to find the maximum flow from the multiple sources to the multiple sinks, we can create a combined source that is connected with infinite capacity arcs to all source nodes and a combined sink that is connected with infinite capacity arcs to all sink nodes.

Assumption 5. *Algorithms whose complexity bounds involve U , assume integrality of the arc capacities.*

There are two cases for the arc capacities: real valued and integral.

DEFINITIONS

s-t path

An *s-t path* is defined as a path starting from node s and ends at node t .

Figure 3. All $s-t$ cuts for a given network.

Cut

A *cut* $[S, \bar{S}]$ partitions the node set N into two nonempty subsets, S and $\bar{S} = N - S$. It consists of all arcs with one end point in S and the other in $\bar{S}$. We refer to the arcs directed from S to $\bar{S}$, denoted by $(S, \bar{S})$, as *forward arcs* in the cut. The cut $[S, \bar{S}]$ is called an *s-t cut* if $s \in S$ and $t \in \bar{S}$. We define the *capacity of the cut* $[S, \bar{S}]$, denoted by $u[S, \bar{S}]$, as $\sum_{(i,j) \in (S, \bar{S})} u_{ij}$ (note that only forward arcs are included). A *minimum cut* in G is an $s-t$ cut of minimum capacity (Fig. 3).

Max-Flow Min-Cut Theorem

The value of the maximum flow from node s to node t in a capacitated network equals the value of the minimum capacity $s-t$ cut.

After determining a maximum flow, a minimum cut can be obtained by a small amount of postprocessing. The minimum-cut problem is the dual of the maximum-flow problem.

Residual Network

The concept of *residual network* plays a central role in the development of maximum flow algorithms. Given a flow x , the residual capacity r_{ij} of any arc $(i, j) \in A$ is equal to $u_{ij} - x_{ij} + x_{ji}$. The residual capacity r_{ij} has two components: (i) $u_{ij} - x_{ij}$, the unused capacity of arc (i, j) , and (ii) x_{ji} , the current flow on arc (j, i) , which we can cancel to increase the flow from node i to node j . We refer to the network $G(x)$ consisting of the arcs with positive residual capacities as the *residual network with respect to the flow x* (Fig. 4).

Distance Labels

A *distance function* $d: N \rightarrow \mathbb{Z}^+ \cup \{0\}$ with respect to the residual capacities r_{ij} is a function from the set of nodes to the set of nonnegative integers. We refer to $d(i)$ as the *distance label* of node i , and distance labels are *valid* with respect to a flow x if they satisfy the following conditions:

$$d(t) = 0; \quad (2a)$$

$$d(i) \leq d(j) + 1$$

for every arc (i,j) in the residual

$$\text{network } G(x). \quad (2b)$$

We say that an arc (i,j) in the residual network is *admissible* if it satisfies the condition that $d(i) = d(j) + 1$; otherwise, we refer to that arc as *inadmissible*. We also refer to a path from node s to node t consisting entirely of admissible arcs as an *admissible path*. An *admissible path* is the *shortest path* (in terms of number of arcs) from the source to the sink.

Complexity

We say that an algorithm is a *polynomial-time algorithm* if its worst case running time is bounded above by a polynomial function of the input size parameters. For a maximum flow problem, the input size parameters are n, m , and $\log U$ (the number of bits needed to specify the largest arc capacity). We refer to a maximum flow algorithm as a

pseudopolynomial-time algorithm if its worst case running time is bounded by a polynomial function of n, m , and U . $O(nmU)$ denotes that the running time is bounded above by some constant multiple of $n m U$ and $\Omega(nmU)$ denotes that the running time is bounded below by some constant multiple of $n m U$. For many years, researchers attempted to find an algorithm faster than the decomposition barrier $\Omega(nm)$. This is a natural lower bound on algorithms that require flow decomposition and on algorithms that augment flow on one arc of a path at a time. Cheriyan *et al.* [3] beat this barrier for dense graphs, while Goldberg and Rao [4] further improve this lower bound.

AUGMENTING PATH ALGORITHMS

The first generation algorithms to solve maximum flow problems are augmenting path algorithms. Let x be a feasible flow in the network G . We refer to a directed path from the source to the sink in the residual network $G(x)$ as an *augmenting path*.

We define the residual capacity $\delta(P)$ of an augmenting path P as the maximum amount of flow that can be sent along it; $\delta(P) = \min\{r_{ij} : (i,j) \in P\}$. Since the residual capacity of each arc in the residual network is strictly positive, the residual capacity of an augmenting path is strictly positive. Sending δ units of additional flow along an augmenting path decreases the residual capacity of each arc (i,j) in the path by δ units and increases the

Figure 4. (a) Original network with arc capacities and a flow x ; (b) the residual network $G(x)$.

residual capacity of the reverse arc (j, i) by δ units.

The generic augmenting path algorithm [5,6] identifies augmenting paths in $G(x)$ and sends flow on these paths until the network contains no such path. We state the algorithm below.

Algorithm. Generic augmenting path algorithm.

```

begin
     $x := 0$ ;
    while  $G(x)$  contains an augmenting
    path do
        begin
            identify an augmenting path  $P$ ;
            augment  $x$  by  $\min \{r_{ij} : (i, j) \in P\}$  units
            along  $P$  and update  $G(x)$ ;
        end
    end

```

When the algorithm terminates, the final residual capacities r_{ij} can be used to construct a maximum flow. Since $r_{ij} = u_{ij} - x_{ij} + x_{ji}$, the arc flows satisfy the equality $x_{ij} - x_{ji} = u_{ij} - r_{ij}$. If $u_{ij} > r_{ij}$, we can set $x_{ij} = u_{ij} - r_{ij}$ and $x_{ji} = 0$; otherwise, we set $x_{ij} = 0$ and $x_{ji} = r_{ij} - u_{ij}$.

The performance of the algorithm depends on (i) the number of augment iterations, and (ii) the time to identify an augmenting path. Both numbers depend on which augmenting path we choose at each iteration. The further discussion on which augmenting paths to choose appears later in the section. We can identify an augmenting path P in $G(x)$ by using a graph search algorithm. A graph search algorithm starts at node s and progressively finds all nodes that are reachable using directed paths. Most search algorithms run in $O(m)$ time, and either identify an augmenting path or conclude that $G(x)$ contains no augmenting paths; the latter happens when the sink node is not reachable from the source node.

In each iteration, the algorithm augments a positive integer amount of flow from the source node to the sink node. To give a bound on the number of iterations, we compute a bound on the maximum flow value. By definition, U denotes the largest arc capacity, and so the capacity of the cut $[\{s\}, N - \{s\}]$

is at most nU . Since the value of any flow can never exceed the capacity of any cut in the network and the algorithm sends at least one unit of flow at each iteration, we obtain a bound of nU on the number of iterations. Consequently, the running time of the algorithm is $O(nmU)$, which is a pseudopolynomial-time bound.

Shortest Augmenting Path Algorithm

The shortest augmenting path algorithm [7] always augments flow along an s - t path in the residual network that has the fewest number of arcs. Since the minimum distance from any node i to the sink node t is monotonically nondecreasing over all augmentations, we reduce the average time per augmentation to $O(n)$.

The shortest augmenting path algorithm proceeds by augmenting flows along *admissible paths*. It constructs an admissible path, incrementally maintaining a partially admissible path, that is, a path from s to a node i consisting solely of admissible arcs, and iteratively performs advance or retreat operations from the last node of the partially admissible path, which we refer to as the *current node*. If the current node i has (i.e., is incident to) an admissible arc (i, j) , then we perform an advance operation and add arc (i, j) to the partial admissible path; otherwise, we perform a retreat operation and backtrack one arc. We repeat these operations until the partial admissible path reaches the sink node, at which time we augment $\min \{r_{ij} : (i, j) \in P\}$ units of flow. We repeat this process until the flow is maximum. We present the algorithm below. Note that $\text{pred}(i)$ is defined as the predecessor of node i on the current path.

Algorithm. Shortest augmenting path algorithm.

```

begin
     $x := 0$ , obtain the exact distance labels  $d$ ;
    current node  $:= s$ ;
    while  $d(s) < n$  do
        begin
            if current node has an outgoing
            admissible arc
                then advance (current node)
            else retreat (current node);
        end
    end

```

```

        if current node =  $t$  then augment;
    end
end
procedure advance ( $i$ )
begin
    let  $(i, j)$  be an admissible arc
     $\text{pred}(j) := i$  and  $i := j$ ;
end
procedure retreat ( $i$ )
begin
     $d(i) := \min\{d(j)+1 : (i, j) \in A \text{ and } r_{ij} > 0\}$ ;
    if  $i \neq s$  then  $i := \text{pred}(i)$ ;
end
procedure augment
begin
    using the predecessor indices identify an
    augmenting path  $P$ ;
    augment  $x$  by  $\min\{r_{ij} : (i, j) \in P\}$  units
    along  $P$ ;
end

```

This algorithm is easy to implement in practice. The resulting algorithms identify at most $O(nm)$ augmenting paths, and this bound is tight; that is, in particular examples, these algorithms perform $O(nm)$ augmentations. The only way to improve the running time of the shortest augmenting path algorithm is to perform fewer computations per augmentation. It can be shown that the use of a sophisticated data structure, called *dynamic trees*, reduces the average time for each augmentation from $O(n)$ to $O(\log n)$ [8]. This implementation of the shortest augmenting path algorithm runs in $O(nm \log n)$ time.

Capacity-Scaling Augmenting Path Algorithm

We start with explaining the *maximum capacity augmenting path algorithm*. The maximum capacity augmenting path algorithm, which was originally developed by Edmonds and Karp [9], always augments flow only along the path with the maximum residual capacity. Let x be any flow, v be its flow value, and v^* be the maximum flow value. Flow decomposition theory shows that in the residual network $G(x)$ we can find m or fewer directed paths from the source to the sink whose residual capacities sum to $(v^* - v)$. Therefore, the maximum

capacity augmenting path has a residual capacity of at least $(v^* - v)/m$. Now consider a sequence of $2m$ consecutive maximum capacity augmentations starting with the flow x . Suppose that v' is the resulting flow value. If in each of these augmentations we augment at least $(v^* - v)/2m$ units of flow, then we will establish a maximum flow within $2m$ or fewer iterations. However, if one of these $2m$ augmentations carries less than $(v^* - v)/2m$ units of flow, $(v^* - v')$ is at most $(v^* - v)/2$ [[1], p. 67]. Since the residual capacity of any augmenting path is between 1 and $2U$, the flow must be maximum in $O(m \log U)$ iterations.

The maximum capacity augmentation algorithm reduces the number of iterations in the generic augmenting path algorithm from $O(nU)$ to $O(m \log U)$. However, the algorithm performs more computations per iteration, since it needs to identify not just any augmenting path but the one with the maximum residual capacity.

We shall now present a variation of the maximum capacity augmenting path algorithm [7] that does not perform more computations per iteration than the generic augmenting path algorithm, and yet establishes a maximum flow within $O(m \log U)$ iterations. Since this algorithm scales the arc capacities implicitly, we refer to it as the *capacity-scaling* algorithm.

We augment flow along a path with a sufficiently large residual capacity instead of a path with the maximum augmenting capacity. We can obtain a path with a sufficiently large residual capacity fairly easily in $O(m)$ time. To define the capacity-scaling algorithm, let us introduce the parameter Δ and define the Δ -residual network as a network containing arcs whose residual capacity is at least Δ with respect to a given flow x . Let $G(x, \Delta)$ denote the Δ -residual network. Note that $G(x, 1) = G(x)$ and $G(x, \Delta)$ is a subgraph of $G(x)$. The algorithm is given below.

Algorithm. Capacity-scaling algorithm.

```

begin
     $x := 0$ ;  $\Delta := 2^{\lfloor \log U \rfloor}$ ;
    while  $\Delta \geq 1$  do
        begin
            If  $G(x, \Delta)$  contains a path from node  $s$ 

```

```

    to node  $t$  then
    begin
        identify a path  $P$  in  $G(x, \Delta)$ ;
        augment  $x$  by  $\min\{r_{ij} : (i, j) \in P\}$ 
        units along  $P$ ;
        update  $G(x, \Delta)$ ;
    end
     $\Delta := \Delta/2$ ;
end
end

```

The capacity-scaling algorithm solves the maximum flow problem within $O(m \log U)$ iterations and runs in $O(m^2 \log U)$ time [9]. Moreover, Ahuja and Orlin [7] improve the running time to $O(nm \log U)$ by using the shortest augmenting path as a subroutine in the step where an augmenting path is identified.

BLOCKING FLOW ALGORITHMS

Instead of identifying augmenting paths one by one, Dinic [10] suggested identifying a set of augmenting paths at each iteration.

Let $d(i)$ be the length of the path with fewest number of arcs from node i to node t . A *layered network* is the subgraph of $G(x)$ that only contains the admissible arcs, that is, (i, j) with $d(i) = d(j) + 1$ (Fig. 5).

A *blocking flow* is the maximum flow in the layered network, and it includes at most m augmenting paths. The flow will be maximum after $n - 1$ blocking flow operations. A blocking flow can be identified in $O(nm)$ time

by using depth-first search or $O(m \log n)$ time by employing dynamic tree structure [8]. The total running times of these algorithms are $O(n^2m)$ and $O(nm \log n)$, respectively. The algorithm is formally given below.

Algorithm. Blocking flow algorithm.

```

begin
     $x := 0$ ;
    while sink is reachable from the source do
    begin
        identify the current layered network;
        find the corresponding blocking flow  $f$ ;
        augment  $x$  by  $f$ ;
        update the residual network;
    end
end

```

Binary Blocking Flow Algorithm

In classical blocking flow algorithms, each arc has a unit length. Goldberg and Rao [4] introduce the blocking flow algorithm with residual capacity-based arc lengths. Let us denote the length of arc (i, j) as

$$l_{ij} = \begin{cases} 0 & \text{if } 2\Delta \leq r_{ij} < 3\Delta, d(i) = d(j), r_{ji} \geq 3\Delta \\ l_{ij} & \text{otherwise,} \end{cases}$$

where

$$l_{ij} = \begin{cases} 0 & \text{if } r_{ij} \geq 3\Delta \\ 1 & \text{otherwise.} \end{cases}$$

The algorithm consists of $O(n \log U)$ Δ -scaling phases. $[S_k, T_k]$ is a canonical cut if $S_k = \{v \in N; d(v) \geq k\}$, $T_k = N - S_k$. We

Figure 5. Forming layered network: (a) residual network; (b) corresponding layered network; (c) layered network after deleting redundant arcs.

denote $[\bar{S}, \bar{T}]$ as the canonical cut with the smallest capacity and $u[\bar{S}, \bar{T}]$ as the capacity of this cut. d_l and $d_{l'}$ are the distance labels in terms of the length functions l and l' , respectively. F is the upper bound on the flow value. The algorithm is given below.

Algorithm. Binary blocking flow algorithm.

```

begin
  current cut :=  $\{s\}, \{N - s\}, F := nU$ ,
   $\Delta := \min\{\lceil F/m^{1/2} \rceil, \lceil F/n^{2/3} \rceil\}$ 
  while  $\Delta \geq 1$  do
    begin
      while  $u[\bar{S}, \bar{T}] > F/2$  do
        begin
          compute  $l'$ ;
          contract strongly connected
            components induced by
            zero-length arcs;
          find a flow of value  $\Delta$  or a
            blocking flow;
          update the residual
            network;
          compute  $l$  and  $d_l$ ;
        end
       $F := u[\bar{S}, \bar{T}]$ , current cut :=  $[\bar{S}, \bar{T}]$ ,
       $\Delta := \min\{\lceil F/m^{1/2} \rceil, \lceil F/n^{2/3} \rceil\}$ 
    end
  end

```

Contracting the strongly connected components is a very important step for the algorithm, since the shortest paths on the residual graph may have admissible cycles because of the zero-length arcs. The algorithm contracts the nodes that are strongly connected with zero-length arcs. Afterward, the flow is routed inside the contracted nodes. The binary blocking flow algorithm runs in $O(\min\{n^{2/3}, \sqrt{m}\}m \log(n^2/m) \log U)$ time.

PREFLOW-PUSH ALGORITHMS

Another class of algorithms for solving the maximum flow problem, known as *preflow-push* algorithms, works with individual arcs rather than paths as compared to augmenting path algorithms. Sending a flow of δ units along a path of k arcs decomposes into k basic operations of sending a flow of δ units along

each of the arcs of the path. We shall refer to each of these basic operations as a *push*.

While a path augmentation maintains conservation of flow at all nodes, the preflow-push algorithms violate conservation of flow at all steps except at the very end, and instead maintain a “preflow” at each iteration. A *preflow* is a vector x satisfying the flow bound constraints (1b) and the following relaxation of the mass balance constraints (1a):

$$\sum_{(j,i) \in A} x_{ji} - \sum_{(i,j) \in A} x_{ij} \geq 0, \text{ for all } i \in N - \{s, t\}.$$

Each element of a preflow vector is either a nonnegative real number or $+\infty$. For a given preflow x , we define the *excess* for each node $i \in N - \{s, t\}$ as follows:

$$e(i) = \sum_{(j,i) \in A} x_{ji} - \sum_{(i,j) \in A} x_{ij}.$$

We refer to a node with positive excess as an *active node*. We adopt the convention that the source and sink nodes are never active. In a preflow-push algorithm, the presence of an active node indicates that the solution is infeasible. Consequently, the basic operation in this algorithm is to select an active node i and try to remove the excess by pushing flow out of it. If we simply push flow to an adjacent node in an arbitrary manner and the other nodes do the same, then it is conceivable that some nodes would continue pushing flow among themselves, resulting in an infinite loop. Ultimately, since we want to send the flow to the sink node, it seems reasonable for an active node to push flow to another node that is “closer” to the sink. If all nodes maintain this rule, then the algorithm could never encounter an infinite loop. The concept of distance labels defined next allows us to implement this algorithmic strategy.

The preflow-push algorithms maintain a *valid distance label* for each node in the network. The basic operation in the preflow-push algorithm is to select an active node i and try to remove the excess by pushing flow to a node with a smaller distance label. If node i has an admissible arc (i, j) , then $d(j) = d(i) - 1$ and the algorithm sends flow on admissible

arcs to relieve the node's excess. If node i has no admissible arc, then the algorithm increments the distance label of node i so that node i has an admissible arc. The algorithm terminates when the network contains no active nodes; that is, excess resides only at the source and sink nodes.

A push of δ units from node i to node j decreases both the excess $e(i)$ of node i and the residual r_{ij} of arc (i, j) by δ units, and increases both $e(j)$ and r_{ji} by δ units. If $\delta = r_{ij}$, the push on arc (i, j) is *saturating*. Otherwise, if $\delta = e(i)$, then the push is *nonsaturating*. The algorithm is given below.

Algorithm. Generic preflow-push algorithm.

```

begin
   $x := 0, d(i) := 0$  for all  $i \in N$ ;
   $x_{sj} := u_{sj}, e(j) = u_{sj}$  for all arc  $(s, j) \in A$ ,
   $e(s) := 0, d(s) := n$ ;
  while  $G(x)$  contains an active node do
    begin
      select any active node  $k$ ;
      if the network contains an admissible
        arc  $(k, j)$  then
        push  $\min\{e(k), r_{kj}\}$  units from  $k$  to  $j$ ;
      else
        replace  $d(k)$  by  $\min\{d(j) + 1 : (k, j) \in A \text{ and } r_{kj} > 0\}$ ;
      end
    end
  end

```

The complexity of the algorithm depends on how we choose an active node. It is possible to show that the preflow-push algorithm maintains valid distance labels at all steps of the algorithm and increases the distance label of any node at most $2n$ times. If we choose any active node, the algorithm performs $O(nm)$ saturating pushes and $O(n^2m)$ nonsaturating pushes. Therefore, the algorithm runs in $O(n^2m)$ time [11].

FIFO Preflow-Push Algorithm

The first-in-first-out (FIFO) preflow-push algorithm [12] examines active nodes in *first-in-first-out* order. The algorithm maintains the set of active nodes as a queue. It selects the node i in front of the queue, performs pushes from this node, and adds new active

nodes/relabelled nodes to the end of queue. The algorithm terminates when the queue is empty.

The first phase consists of those node examinations for the nodes that become active during the preprocess operation. The second phase consists of node examinations of all the nodes that are in the queue after the algorithm has examined the nodes in the first phase. Similarly, the third phase consists of the node examinations of all the nodes that are in the queue after the algorithm has examined the nodes in the second phase, and so on.

It can be shown that the algorithm performs at most $2n^2 + n$ phases. Each phase examines any node at most once, and each node examination performs at most one nonsaturating push. Therefore, a bound of $2n^2 + n$ on the total number of phases would imply a bound of $O(n^3)$ on the number of nonsaturating pushes. This result would also imply that the FIFO preflow-push algorithm runs in $O(n^3)$ time, because the bottleneck operation in the generic preflow-push algorithm is the number of nonsaturating pushes.

Highest Label Preflow-Push Algorithm

The highest label preflow-push algorithm always pushes flow from an active node with the highest distance label. Let $h^* = \max\{d(i) : i \text{ is active}\}$. The algorithm first examines nodes with distance labels equal to h^* and pushes flow to nodes with distance labels equal to $h^* - 1$. In turn, these nodes push flow to nodes with distance labels equal to $h^* - 2$, and so on, until either the algorithm relabels a node or it exhausts all the active nodes. When it relabels a node, the algorithm repeats the same process. Note that if the algorithm does not relabel any node during n consecutive node examinations, then all the excess reaches the sink (or the source) and the algorithm terminates. Since the algorithm performs at most $2n^2$ relabel operations, we immediately obtain a bound of $O(n^3)$ on the number of node examinations. Since each node examination entails at most one nonsaturating push, the highest label preflow-push algorithm performs $O(n^3)$ nonsaturating pushes.

We use the following data structure to select a node with the highest distance label without spending too much effort. For each $k = 1, 2, \dots, 2n - 1$, we maintain the list

$$\text{LIST}(k) = \{i : i \text{ is active and } d(i) = k\}$$

in the form of either linked stacks or linked queues (see Ref. 13, pp. 200–204, for information on stacks and queues). We define a variable *level*, which is an upper bound on the highest value of k for which $\text{LIST}(k)$ is nonempty. In order to determine a node with the highest distance label, we examine the lists $\text{LIST}(\text{level})$, $\text{LIST}(\text{level}-1)$, $\dots$, until we find a nonempty list, say $\text{LIST}(p)$. We set the level equal to p and select any node in $\text{LIST}(p)$. Moreover, while examining a node, if its distance label increases, then we set the level equal to the new distance label of the node. Observe that the total increase in level is at most $2n^2$, and so the total decrease is at most $2n^2 + n$. Consequently, scanning the lists $\text{LIST}(\text{level})$, $\text{LIST}(\text{level}-1)$, $\dots$ in order to find the first nonempty list is not a bottleneck operation.

Cheriyān and Maneshwari [14] show that the number of nonsaturating pushes is $O(n^2\sqrt{m})$. The highest label preflow-push algorithm is currently the most efficient method for solving the maximum flow problem in practice, because it performs the least number of nonsaturating pushes. Cherkassy and Goldberg [15] exhibit a family of problems for which the running time of all implementations they consider is quadratic. They show that the highest label preflow-push algorithm with global and gap relabeling heuristics is the fastest algorithm for all problem classes that they studied.

Excess-Scaling Algorithm

Excess-scaling algorithm is another version of the generic preflow-push algorithm that pushes preflows only from the active nodes with large excess. The algorithm is given below.

Algorithm. Excess-scaling algorithm.

begin

$x := 0, d(s) := n, d(t) := 0, d(i) := 1$
for $i \in N - \{s, t\}$;

set x_{sj} and $e(j)$ to u_{sj} for all arcs $(s, j) \in A$,
and $\Delta := 2^{\lceil \log U \rceil}$;
while $\Delta \geq 1$ **do**
 begin
 if $G(x, \Delta)$ contains an active node with
 excess more than $\Delta/2$ **then**
 begin
 select node i with excess more than
 $\Delta/2$ and the smallest distance label;
 if the network contains an admissible
 arc (k, j) **then**
 push $\min\{e(k), r_{kj}, \Delta - e(j)\}$ units
 of flow from k to j ;
 else
 update $d(k) = \min\{d(j) + 1 :$
 $(k, j) \in A \text{ and } r_{kj} > 0\}$
 end
 $\Delta := \Delta/2$;
 end
 end

The excess-scaling algorithm runs in $O(nm + n^2 \log U)$ time [16]. Ahuja *et al.* [17] obtain the improved version by (i) increasing the scale factor from 2 to k (Δ becomes Δ/k in the next phase), and (ii) choosing the excess node with the highest distance label. This version runs in $O(nm \log(n/m\sqrt{\log U}))$ time.

OTHER ALGORITHMS

In this article, we briefly mention the other approaches to solve maximum flow problems.

Malhotra, Kumar, and Maheshwari (MPM) Algorithm

This algorithm relies on the idea of selecting the node with the lowest flow potential, $p_x(i)$, that is, the maximum amount of flow that can be forced through a node.

$$p_x(i) = \min \left\{ \sum_{(j,i) \in A} (u_{ji} - x_{ji}), \sum_{(i,k) \in A} (u_{ik} - x_{ik}) \right\}.$$

Algorithm. MPM algorithm.

begin

$x := 0$;
while there are nodes in the
network **do**
 begin
 select the node k with minimum

```

        flow potential;
        send  $p_x(k)$  units of flow from node  $k$ 
            toward the node  $s$  and  $t$ ;
        augment  $x$  by  $p_x(k)$ , update  $G(x)$ ;
        delete all saturated arcs, node  $k$ , and
            the nodes with only incoming or
            outgoing arcs;
    end
end

```

Since at the last step in the while loop at least one node will be deleted, this loop will be executed at most n times.

Maximum Adjacency Ordering Algorithm

The ordering of nodes $v_1, v_2, \dots, v_n$ is called maximum adjacency (MA) ordering if for all i , v_i is the node in $N - \{v_1, v_2, \dots, v_{i-1}\}$ that has the largest sum of the residual capacities of the arcs to the nodes $v_1, v_2, \dots, v_{i-1}$.

MA ordering algorithm is proposed by Fujishige [18] and runs in $O(n(m + n \log n) \log n U)$ time and the scaling version runs in $O(nm \log U)$ time. Shioura [19] shows that the algorithm is not strongly polynomial by giving a real-valued instance for which the algorithm does not terminate. Matsuoka and Fujishige [20] propose an improved version of Fujishige's algorithm using preflows. While the theoretical bound is the same Fujishige [18], the algorithm is faster in practice.

Arc-Balancing Algorithm

Tarjan *et al.* [21] present a round-robin arc-balancing algorithm that computes a maximum flow in $O(n^2 m \log(nU))$ time. Although this algorithm is slower than other known algorithms, it is extremely simple. This algorithm maintains a *pseudoflow* rather than a preflow. Let x be a pseudoflow then $x_{ij} = -x_{ji}$ and $x_{ij} \leq u_{ij}$ for all arcs $(i, j) \in A$. Moreover, the balance at node i can be calculated as

$$b(i) = \sum_{(j,i) \in A} x_{ji},$$

where $b(i)$ can take both positive (excess) and negative (deficit) values.

Algorithm. Arc-balancing algorithm.

```

begin
    Construct an initial pseudoflow by
        saturating every arc out of  $s$  and every
        arc into  $t$ , and assigning zero flow to
        every other arc.
    while (sum of positive balances  $> 1$ ) and
        (sum of negative balances  $< -1$ ) do
        begin
            choose an arc  $(v, w)$  with  $b(v)$ 
                 $> b(w)$ ,  $w \neq s$ , and  $v \neq t$ ;
            increase the flow on  $(v, w)$  by
                 $\min\{r_{vw}, e(v)/2 - e(w)/2\}$ ;
        end
    end
end

```

Hochbaum's Pseudoflow Algorithm

Hochbaum [22] proposes a pseudoflow algorithm that runs in $O(mn \log n)$ time. Chandran and Hochbaum [23] show that the highest label pseudoflow implementation is faster than the preflow-push counterpart in most of the instances across different problem families. Hochbaum and Orlin [24] show that the highest label version of the pseudoflow algorithm has complexities $O(mn \log n^2/m)$ and $O(n^3)$ with and without the use of dynamic trees, respectively.

MAXIMUM FLOW ON SPECIAL GRAPHS

Frequently, it is possible to solve flow problems on special networks more efficiently than those defined on general capacity networks. In this section, we identify three special networks.

Flows in Unit Capacity Networks

Some combinatorial problems are naturally formulated as 0–1 optimization models. When viewed as flow problems, these models yield networks whose arc capacities are all 1, which are referred to as *unit capacity networks*. In this section, we describe *unit capacity maximum flow algorithm* [7].

In a unit capacity network, the maximum flow value is at most n since the capacity of the s – t cut $[s, S - s]$ is at most n . Therefore, general augmenting path algorithm determines a maximum flow within n

augmentations and requires $O(nm)$ effort. The shortest augmenting path algorithm also solves this problem in $O(nm)$ time since its bottleneck operation, which is the augmentation step, requires $O(nm)$ time instead of $O(n^2m)$ time. The unit capacity maximum flow algorithm that we describe is a hybrid version of these two algorithms

requires only $O(\min\{n^{2/3}m, m^{3/2}\})$ time, which is consistently better than the $O(nm)$ bound of either algorithm by itself. This algorithm runs in $O(n^{1/2}m)$ time for a simple network. A unit capacity network is called a *simple network* if either the number of incoming arcs or the number of outgoing arcs of each node is at most one.

Algorithm. Unit capacity maximum flow algorithm.

begin

 apply the shortest augmenting path algorithm until $d(s) \geq \min\{2n^{2/3}, m^{1/2}\}$;
 then apply the general augmenting path algorithm until establishing the maximum flow;

end

Flows in Bipartite Networks

A bipartite network is a network $G = (N, A)$ with a node set N partitioned into two subsets, N_1 and N_2 , so that for every arc $(i, j) \in A$, either $i \in N_1$ and $j \in N_2$, or $i \in N_2$ and $j \in N_1$. We often represent a bipartite network using the notation $G = (N_1 \cup N_2, A)$. Let $n_1 = |N_1|$ and $n_2 = |N_2|$.

In this section, we describe an adaptation of the preflow-push algorithms that we considered in the previous discussion in this article. The worst case behaviors of these special-purpose algorithms are similar to those of the original algorithms if the node sets N_1 and N_2 are of comparable size. Without any loss of generality, we

assume that $n_1 \leq n_2$ and the source node is in N_2 .

As an example of the type of results that we obtain, we show the specialization of the generic preflow-push algorithm. We refer to this algorithm as the *bipartite preflow-push algorithm*. The running time is $O(n_1^2m)$ time and if $n_1 < n_2$ then the new implementation is considerably faster than the original algorithm [24]. The ideas that we consider also apply in a straightforward manner to FIFO, highest label, preflow-push, and excess-scaling algorithms and yield algorithms with improved worst case complexity. We just include the push/relabel procedure since the remaining parts of the algorithms are the same.

Algorithm.

procedure *bipartite push/relabel*(i);

begin

if the residual network contains an admissible arc (i, j) **then**

if the residual network contains an admissible arc (j, k) **then**

 push $\delta = \min\{e(i), r_{ij}, r_{jk}\}$ units of flow over the path $i \rightarrow j \rightarrow k$ and augment x by δ ;

else replace $d(j)$ by $\min\{d(k) + 1 : (j, k) \in A \text{ and } r_{jk} > 0\}$;

else replace $d(i)$ by $\min\{d(j) + 1 : (i, j) \in A \text{ and } r_{ij} > 0\}$;

end

Flows in Planar Networks

Planar networks can be drawn on the plane so that no two arcs intersect each other. Itai and Shiloach [25] present an algorithm that needs $O(n \log n)$ computations for undirected planar networks.

This algorithm first constructs the dual network and solves the shortest path problem over it. The shortest path in the dual network yields a minimum cut in the original network and the shortest path distances yield a maximum flow. Borradaile and Klein [26] recently

Table 1. Summary of the Algorithms

Augmenting path algorithms		# Augment iterations	Time to find an augmenting path	Best running time
Generic [5,6]		$O(nU)$	$O(m)$	$O(nmU)$
Shortest augmenting path [7,8]		$O(nm)$	$O(\log n)$	$O(nm \log n)$
Capacity scaling [7,9]		$O(m \log U)$	$O(n)$	Dynamic tree implementation $O(nm \log U)$
Blocking flow algorithms		# Blocking flows	Time to find a blocking flow	Best running time
Blocking flow [10]		$O(n)$	$O(nm)$	$O(n^2m)$
Sleator and Tarjan [8]		$O(n)$	$O(m \log n)$	$O(nm \log n)$
Binary blocking flow [4]		$O(\min(n^{2/3}, \sqrt{m}) \log U)$	$O\left(m \log \frac{n^2}{m}\right)$	Dynamic tree implementation $O(\min(n^{2/3}, \sqrt{m})m \log \frac{n^2}{m} \log U)$
Preflow-push algorithms		Notes	# Nonsaturating pushes	Best running time
Generic [11]		The number of saturating pushes is $O(nm)$	$O(n^2m)$	$O(n^2m)$
13	FIFO [12]	Chooses the active nodes in first-in-first-out order	$O(n^3)$	$O(n^3)$
	Highest label [11] with dynamic trees	Chooses the active node with the highest label	$O(n^3)$	$O(nm \log(n^2/m))$
	Highest label [14]	Chooses the active node with the highest label	$O(n^2 \sqrt{m})$	$O(n^2 \sqrt{m})$
Excess scaling [16]		Chooses the large excess node with the smallest distance label	$O(n^2 \log U)$	$O(nm + n^2 \log U)$
Excess scaling with dynamic trees [17]		Extension of [16]	Wave scaling:	Wave scaling:
		Uses a scale factor (k) greater than 2	$O(n^2 \sqrt{\log U})$	$O(nm + n^2 \sqrt{\log U})$
		Chooses the large excess node with the highest distance label	Stack scaling: $O\left(\frac{n^2 \log U}{\log \log U}\right)$	Stack scaling: $O\left(nm + \frac{n^2 \log U}{\log \log U}\right)$
				Dynamic tree implementation runs in $O(nm \log(n \sqrt{\log U}/m + 2))$

(continued overleaf)

Table 1. (Continued)		
Other algorithms	Notes	Best running time
MPM [27]	—	$O(n^3)$
MA ordering [18]	Sorts nodes according to maximum adjacency Capacity scaling version Practically better than [11,27]	$O(n(m + n \log n) \log nU)$ $O(nm \log U)$ Preflow version [20] $O(n(m + n \log n) \log nU)$
Arc-balancing [21]	Uses pseudoflows	$O(n^2m \log (nU))$
Hochbaum's [22]	Uses pseudoflows	$O(mn \log n)$ Highest label [24] $O(mn \log n^2/m)$ Highest label with dynamic tree [24] $O(n^3)$

introduced an $O(n \log n)$ algorithm for the planar directed networks. A planar network with a source node s and a sink node t is called s - t planar if both nodes lie at the boundary of the unbounded face. There are also special algorithms for s - t planar networks.

SUMMARY OF ALGORITHMS

The majority of the best theoretical time bounds for maximum flow problems are based on the preflow-push type of algorithms: The algorithm proposed by Goldberg and Tarjan [11] runs in $O(nm \log(n^2/m))$ time; Ahuja *et al.* [17] runs in $O(nm \log(n/m\sqrt{\log U} + 2))$ time. Cheriyan *et al.* [3] have a random arc selection rule and run in $O(n^3/\log n)$ time and $O(nm + (n \log n)^2)$ time with high probability. King *et al.* [28] present the deterministic version of Cheriyan *et al.* [3] that runs in $O(nm + n^2 + \varepsilon)$ time for any constant $\varepsilon > 0$. The best preflow-push algorithms currently outperform the best augmenting path algorithms in theory as well as in practice (see, for example, Ahuja *et al.* [12]). Chandran and Hochbaum [23] show that the pseudoflow algorithms run faster than the preflow-push algorithms for most of the problem instances.

The presented algorithms for general networks are summarized in Table 1. For each algorithm, we reported the references, some highlights, and the decomposition of the running time. The algorithms with more than one references are improved over time; therefore we only report the best running time.

MDP BASIC COMPONENTS

JONATHAN PATRICK
Telfer School of Management,
University of Ottawa,
Ottawa, Ontario, Canada

THE BASICS OF MARKOV DECISION PROCESSES

The article entitled, *Historical Development of MDP Theory*, represented an overview of how Markov decision process (MDP) theory evolved over the last century. From those initial forays at such places as the RAND Corporation in Santa Monica, California, MDP models have found applications in any number of research areas including medical decision making [1,2], health care management [3,4], forestry [5], fisheries [6] and business [7–9]. The types of problems solved include scheduling [4], capacity planning [5], revenue management [7–9], supply chain and policy analysis.

THE FIVE COMPONENTS OF AN MDP MODEL

MDP models are mathematical methods for solving sequential decision problems where the decision taken today impacts what actions are possible tomorrow. MDP models are divided into numerous categories depending on the length of the decision process (infinite or finite horizon) and whether decisions are taken at regular intervals (discrete time models) or at random times, the length of which is triggered by some event (continuous time models). A description of the five major components of an MDP model: decision epochs, states, actions, transition probabilities, and rewards (or costs) is provided below. They allow the modeler to formulate a wide array of sequential decision problems that can then be solved to find the

optimal decision policy on the basis of the optimization methods developed in other articles within this encyclopedia.

Decision Epochs

The simplest form of an MDP is a *finite horizon, discrete time* model. In such a model, a finite number of decisions are taken at fixed, regular intervals. The time at which a decision is taken is called a *decision epoch*. In this article, the letter N is used to represent the number of decision epochs. The article entitled *Finite Horizon MDPs* deals with the methods for solving these *finite horizon discrete time* problems. If N is allowed to go to infinity so that there are an infinite number of decision epochs, then the methods for solving these problems become more complex but the basic form of the MDP as described in this article remains essentially the same. (See the articles entitled *Total Expected Discounted Reward Criterion*, *Total Expected Reward Criterion*, and *Average Reward Criterion* for methods for solving *infinite horizon discrete time* problems.) One of the most well-known discrete time MDP models involves solving the inventory management problem. Many variations of this problem are possible, but to illustrate the basic MDP concepts, consider a simple version. In this problem, a manager is in charge of managing the inventory of a store that sells a single product type. The store earns revenue by selling the product to customers. Demand for the product is assumed to be variable. The inventory level decreases when the items are sold to customers, and backorders are not allowed; that is, if there is insufficient inventory to meet demand then the excess demand is lost. The manager replenishes the inventory by deciding when to order new inventory from a single supplier and how much to order. There is a cost associated with placing an order and a cost associated with holding inventory. The manager's goal is to make inventory decisions in a way that maximizes the store's net profit. Thus, decisions are made at discrete intervals

(each day at 9 a.m. for instance) and could potentially be framed as a finite horizon MDP (i.e., if stocking for a season) or as an infinite horizon MDP (if running a business for the foreseeable future).

Alternatively, there are other applications where it does not make sense to assume that decisions are made at regular intervals. Suppose, for instance, that a manager is in charge of insuring that a queue does not build up at a given workstation in a factory. It is assumed that the rate at which products are serviced is under his control. (He may be able to increase the speed of service or else introduce additional servers.) Usually there is a cost associated with increasing the rate of service and a cost associated with each customer waiting in the queue. Thus, there is a balance to be struck between keeping the queue small and not incurring too much cost for running at a speedier service rate. In such a case, it would make sense to reevaluate after each new product arrival and after each new service completion. But these are random events and thus the decision epochs do not occur at fixed intervals. Such applications are modeled as *continuous time MDPs* (see the article entitled *Continuous-time MDPs*).

States. Clearly, in order to solve a decision problem, the model must have some means of tracking the information necessary for making an informed decision. For instance, if one is trying to solve the inventory management problem then it is paramount that the current inventory level be known each time a decision is made. The *state* of the system at decision epoch t , often denoted by s_t , is the current value of all relevant information required in order to make an informed decision. We need only concern ourselves with information that can change from decision epoch to decision epoch as unchanging information can be left as input to the model. The *state space*, S_t , is the set of all possible values of the state variable(s) at time t . Thus, in the inventory management problem, the state space might be $S_t = 0, 1, \dots, M$, where M is the maximum number of items that the store can hold. (If backorders are allowed, then the state space would expand to include the negative integers in order to represent a backlog of demand.)

In this example, the state space is a finite set of integers. However, in other instances, the state space might be a continuous range (i.e., the level of water in a reservoir) or an infinite set of discrete numbers (i.e., clients waiting for service in a system with an infinite buffer).

More complicated states and state spaces that involve more than one state variable are also possible. For instance, in advanced appointment scheduling, the state space must include the number of available appointment slots in each day of the booking horizon as well as the number of clients waiting to be booked. Such a complicated state space quickly runs into the *curse of dimensionality* that renders the optimization methods developed in the articles mentioned earlier intractable. This curse refers to the fact that as the dimensions in the state vector increases, the size of the state space grows dramatically. Traditional MDP solutions present a look-up table that gives the optimal action to take in every state and at every decision epoch. If the state space is too large, this is simply not feasible. The article entitled *Large-Scale MDPs* deals with methods for approximating a solution to these larger and more complex MDP models.

Actions. The third component of an MDP model is the set of *actions* available to the user. Clearly, what actions are available will most often depend on the state of the system. For instance, if the inventory level is at $M-1$ then the only action available to the manager is not to order any new items or to order only one. The *action space* at decision epoch t is the set of available actions for the current state, s_t , and is usually denoted by $A_t(s_t)$. The action chosen at decision epoch t is denoted by a_t . Again, the action space need not be a finite set of integer values as in the inventory example. It could equally be a continuous range (i.e., how much additional water to remove from a reservoir) or an infinite set of discrete numbers (i.e., the number of waiting clients to refuse service in a system with an infinite buffer).

Transition Probabilities. The fourth component required for solving a sequential decision problem is how the system evolves

from one decision epoch to the next. These are called the *transition probabilities*. In the inventory management problem, the state at the next decision epoch will equal the current inventory level plus any new orderings minus any demand that arrives between now and the next decision epoch. As no backorders are allowed (by assumption), the new inventory level will be zero if demand exceeds the current inventory plus newly ordered items. Notice the further assumption that there is no lag time in delivery. While including a lag time is quite possible, it complicates the model and thus makes it less useful for illustrative purposes. The value of the next state can be written formally as

$$s_{t+1} = \max\{s_t + a_t - D_t, 0\},$$

where D_t is a random variable representing the demand that arrives between decision epochs t and $t + 1$. The above equation is an example of a state transformation function. The transition probabilities would therefore depend on the arrival distribution of new demand as well as the current state and action. They are often denoted by $p_t(s_{t+1}|s_t, a_t)$, which represents the probability of being in state s_{t+1} at decision epoch $t + 1$ given that at decision epoch t the system was in state s_t and action a_t was taken.

Rewards or Costs. Finally, if a decision process is to be optimized then there clearly needs to be some form of *reward* or cost that determines what actions are better than others. This is the fifth and final piece of an MDP model. In the most general setting, these rewards might depend on the current state of the system, the action taken and even the state of the system at the next decision epoch and are often denoted by $r_t(s_t, a_t, s_{t+1})$. Returning once again to the inventory example, the reward function should include a holding cost, $h()$, for storing inventory, an ordering cost, $O()$, and a revenue function, $f()$, for any sales.

Formally, this can be written as

$$r_t(s_t, a_t, s_{t+1}) = -O(a_t) - h(s_t + a_t) + f(s_t + a_t - s_{t+1}^+)$$

A typical ordering cost function would include a fixed cost for any size order placed as well as a variable cost as the size of the order increases. Since the state of the system at the next decision epoch is generally not known in advance, the typical MDP works with the expected reward based on the current state and action. This is given by

$$r_t(s_t, a_t) = \sum_{s_{t+1} \in S} r(s_t, a_t, s_{t+1}) p_t(s_{t+1}|s_t, a_t).$$

In a finite horizon model, a salvage function, $g(s_N)$, denotes the value of being in state s_N at the end of the planning horizon. It is assumed that there is no action to be taken at the final decision epoch. Most inventory management problems are more reasonably modeled as infinite horizon problems; however, there are some instances (seasonal products) where a finite horizon is more logical.

The reward structure is somewhat more complicated in continuous time models as the length of time between decision epochs will vary (possibly impacting on the reward or cost). The reader is referred to the article entitled *Continuous-Time MDPs* for a discussion of the differences.

A Markov process is said to be *stationary* if both the reward functions and the transition probability matrices are the same for every decision epoch; that is $r_t(s_t, a_t) = r(s_t, a_t)$ and $p_t(s_{t+1}|s_t, a_t) = p(s_{t+1}|s_t, a_t)$ for all states s_{t+1} and s_t and all actions a_t . If this is not the case, then the Markov process is said to be *non-stationary*. Infinite horizon models assume that the Markov process is stationary.

DECISION RULES AND POLICIES

The above five components formally define an MDP model. The next step is to determine the optimal decision policy. A *decision rule*, d_t , is defined as a function that dictates what decision to take for each possible state at decision epoch t . Decision rules may

be *history dependent* if the decision taken depends on the entire history up to that decision epoch or they may be *Markovian* if they depend only on the current state of the system. Decision rules may also be *deterministic* (if they dictate only one given action for each state) or they may be *randomized* (if they give a probability distribution over the set of possible actions that is used to randomly determine the appropriate action). History dependent policies are extremely difficult to analyze (largely because the state vector quickly becomes too large for tractability if the entire history needs to be included) and can often be avoided by properly structuring the state space. Moreover, under mild assumptions, it can be shown [10] that there exists a deterministic decision rule that does at least as well as any randomized one. Thus, the focus is commonly on deterministic Markovian decision rules, $d_t : S_t \rightarrow A_t(s_t)$, that map each possible state to a specific feasible action.

A policy, $\pi = (d_1, d_2, d_3, \dots, d_N)$, is a set of decision rules (one for every decision epoch) that dictates what action to take for any given state and at any given decision epoch. A policy is *Markovian* if the decision rule for each decision epoch is *Markovian* and *deterministic* if each decision rule is *deterministic*. Since it is possible, under mild assumptions, to show that there always exists an optimal policy that is Markovian and deterministic (given the objectives discussed below) [10], the rest of the article restricts discussion to this subset of all possible policies.

A policy is said to be *stationary* if, for each decision epoch, the same decision rule is used [i.e., $\pi = (d, d, d, \dots, d)$]. In finite horizon models, the optimal policy is rarely stationary as the best action invariably changes as the end of the horizon approaches. Consider again the inventory example. As the season for a given product approaches its end, it is clearly advantageous to carry less inventory so as not to be left at the end of the season with significant inventory that usually is sold off for a reduced price or may even have to be absorbed as a loss. However, in the infinite horizon setting, it is intuitively reasonable to assume that a stationary policy will in fact be optimal as there is no

substantive difference between the decision process at decision epochs t and $t + 1$ provided the horizon is infinite and the rewards and transitions are independent of t . Thus, for infinite horizon models, the set of stationary policies plays an important role.

DEFINING THE APPROPRIATE GOAL

The natural goal is to find the policy, π^* , that gives the greatest total reward over the length of the horizon. Formally, the total reward of a policy π over a finite horizon of length N and starting at state s is defined as

$$v_N^\pi(s) = E_s^\pi \left\{ \sum_{t=1}^N r_t(X_t, Y_t) + r_N(X_N) \right\},$$

where X_t is a sequence of random variables representing the progression of the state and Y_t is a sequence of random variables representing the actions taken at each decision epoch. Actions are determined using the policy π . v_N^π is called the *value function* of the policy π . (In the infinite horizon setting, the subscript N is dropped.) Ideally, one would like to find a policy π^* such that

$$v_N^{\pi^*}(s) \geq v_N^\pi(s),$$

for all starting states s and for all alternative policies π . This would seem to be a fairly daunting task, especially if the planning horizon is long. The genius of MDP theory was to realize that such a problem could be solved one decision epoch at a time rather than trying to solve the whole decision problem at once. The process is called backward induction (see the article entitled *Finite Horizon MDPs*) as it starts in the last period in which there is a decision, period $N-1$, and moves back to period 1.

However, in the infinite horizon setting, the total expected reward often turns out to be problematic due to the fact that the sum of rewards is now infinite and therefore

1. may not even exist;
2. if it does exist, may have no policy that achieves the maximum; and

3. may be infinite for a number of different policies that are not all equally good policies. (For instance, it would be infinite both for a policy that yields a reward of \$1 for every decision epoch and one that yields \$100 for every decision epoch.)

One of two solutions is generally employed when the total expected reward is inappropriate. The first solution introduces a discount factor that causes rewards to be valued less highly the further into the future they are realized and finds the policy that gives the greatest total *discounted* reward over the infinite horizon (see the article entitled *Total Expected Discounted Reward Criterion*). This objective has the advantage of being guaranteed to exist and favors policies with upfront rewards. The second solution is to find a policy with the greatest *average* reward per decision epoch instead (see the article entitled *Average Reward Criterion*). Which objective is employed depends on what best suits the application.

THE FORM OF AN OPTIMAL POLICY

One of the benefits of MDP theory is that, in some instances, it is possible to prove that the optimal policy has a certain form independent of the actual parameter values. For instance, in the inventory management problem with no backlogs and over an infinite horizon, it has been proven that the optimal policy is an (s, S) policy. Such a policy places an order as soon as the inventory level drops below s and orders enough to make the post-decision inventory equal to S . This form of the policy holds true for a whole range of holding and ordering costs as well as transition probabilities. Such structural results provide useful insight into a wide variety of sequential decision problems, are often easy to implement, and can even help reduce the computational burden associated with finding an optimal policy. Such results are discussed in the article entitled *Structured MDP Policies*.

CONCLUSION

The above formulation of an MDP model allows for significant flexibility and therefore covers a broad range of potential instances of sequential decision problems. From scheduling patients in health care, to planning capacity in airlines or managing inventory in retail, the potential of MDP theory to improve practice is undeniable. Other articles in this encyclopedia will introduce the reader to a number of optimization methods for solving finite or infinite horizon, discrete or continuous time models. Further, the reader will be introduced to methods for dealing with instances where the state information is only an approximation of the true state (see the article entitled *Partially Observable MDPs*) and with more complex methodologies that seek to overcome some of the persistent limitations of the standard methods for solving MDPs (see the article entitled *Large Scale MDPs*). For more in-depth studies of MDP theory, the reader is referred to Richard Bellman's classic book *Dynamic Programming* [11] as well as more recent works by Puterman [10], Bertsekas [12] and Feinberg [13].

MEASURES OF RISK EQUITY

L. ROBIN KELLER

YITONG WANG

The Paul Merage School of
Business, University of
California Irvine, Irvine,
California

TIANJUN FENG

Fudan University, School of
Management, Shanghai,
China

This article covers measures of fairness or equity for situations involving risk, as represented with a probability distribution over outcomes, which often include adverse health or safety outcomes. For an introduction to fairness, the reader is referred to Keller *et al.* [1]. Such risk equity measures may be used in societal utility functions to identify preferred policies from the perspective of what is good for society as a whole. The aim of this article is to present enough detail on this topic so that a person can understand the basic concepts and find further references to get more details; this is not a complete compilation of all the research in this field.

Suppose two policies are being considered to improve public safety, and only one policy can be funded.

Safety Policy Scenario

Policy A: Install emergency phones along roadsides; this will save 10 lives annually.

Policy B: Install a flood warning system, with a 50% chance of saving 20 lives annually (when flood occurs and assume one flood only in that year) and a 50% chance of saving no lives (when no flood occurs).

One way of evaluating such alternative societal risk policy options might be to calculate expected fatalities, then choose the

policy with the maximum number of lives saved. However, in this case, the expected number of lives saved is 10 for both policies.

To go beyond using the objective of maximizing expected number of lives saved to make this choice, one could construct a societal utility function over the number of lives. The utility of policy A is $u(A) = u(10 \text{ lives saved})$. The utility of policy B is $u(B) = 0.50u(20 \text{ lives saved}) + 0.50u(0 \text{ lives saved})$. A risk-averse utility function would favor the choice of policy A, with the sure number of 10 lives saved. A risk-prone utility function would favor the choice of policy B.

While specifying a risk-averse or risk-prone utility function in this scenario will lead to a clear choice in this case, more generally one may wish to consider how these fatalities are distributed among the members or groups of society. In policy A, 10 lives are saved each year, from separate roadside incidents. In policy B, if there is a flood during a year, 20 lives will be saved from that one flood, and in nonflood years, no lives will be saved.

Keeney and Winkler [2] point out that

In evaluating public risks, it may be useful to separate three issues:

1. The undesirability of fatalities, aside from equity considerations.
2. *Ex post* equity, meaning the equity associated with the fatalities that actually occur.
3. *Ex ante* equity, meaning the equity of the process and risks which eventually lead to the fatalities.

See the following sections titled “*Ex Ante* Equity,” “*Ex Post* Equity,” “Catastrophe Avoidance,” and “Envy-Free Allocation,” for details. The section titled “Decision Models Containing Equity Measures” presents equity models and applications. For other papers on the use of utility functions to represent preferences regarding societal equity, see Keeney [3–5], Broome [6], Fishburn [7], and Sarin [8].

EQUITY AXIOMS

Individual Equity

Suppose there are two people at potential risk. (We often begin to examine equity measures by simplified scenarios involving just two people, and then extend the concepts to n people.) The concept of *individual equity* is that *society is indifferent if the two people switch their risk of being the sole person to die and everything else stays the same.*

This preference is contained in Fishburn's [7] *individual equity axiom E1*. To set up the notation for his axioms, which are stated for just two people, denoted as 1 and 2, he first identifies the four basic consequences and the chances of each:

- p chance that
(Person 1 lives, Person 2 dies),
- q chance that
(Person 1 dies, Person 2 lives),
- r chance that (Person 1 lives,
Person 2 lives) = both live, and
- $1 - (p + q + r) = \#$ chance that
(Person 1 dies, Person 2 dies) = both die.

We will arbitrarily scale the societal utility function with two end points: Suppose that the certainty (i.e., the probability $r = 1$) that both live has utility 2 and the certainty (i.e., the probability $1 - (p + q + r) = 1$) that both die has utility 0. Denote the utility of person 1 living alone as a_1 and the utility of person 2 living alone as a_2 , with both a_1 and a_2 between 0 and 2.

Having set the utility of both people dying as 0 (the minimum possible utility) and the utility of both people living as 2 (the maximum possible utility), there are only two remaining utilities to specify. They are

a_1 = the utility of person 1 living and
person 2 dying

a_2 = the utility of person 1 dying and
person 2 living.

These utilities (a_1 and a_2) might be equal to each other or unequal. They might both

equal 1, or both be under 1 or above 1, and so on. Different equity axioms lead to specific possible ranges of values for the utilities of these two intermediate outcomes.

For each decision scenario, we want to represent the societal utility for a policy which will result in the four basic consequences with some probability of each. This societal utility can be conveniently written, using the probabilities of the four basic consequences, and suppressing the detailed description of the consequences, as

$$u(p, q, r, 1 - (p + q + r)).$$

(We will use this short-hand notation whenever we present Fishburn's axioms in the sections on equity axioms.)

So, we compute the vonNeumann–Morgenstern expected utility of a policy as follows:

$$\begin{aligned} u(\text{policy}) &= u(p, q, r, 1 - (p + q + r)) \\ &= pu(\text{Person 1 lives, Person 2 dies}) \\ &\quad + qu(\text{Person 1 dies, Person 2 lives}) \\ &\quad + ru(\text{Person 1 lives, Person 2 lives}) \\ &\quad + (1 - (p + q + r))u(\text{Person 1 dies,} \\ &\quad \text{Person 2 dies}) \\ &= p(a_1) + q(a_2) + r(2) + (1 - (p + q + r))0 \\ &= a_1p + a_2q + 2r \end{aligned}$$

Different equity axioms result in different possible values of $u(\text{Person 1 lives, Person 2 dies}) = a_1$ and $u(\text{Person 1 dies, Person 2 lives}) = a_2$.

Using our notation, the assumption of *individual equity* is that

$$u(p, q, r, \#) = u(q, p, r, \#),$$

where $\#$ represents the probability of the fourth consequence = $1 -$ the sum of the first three probabilities, which, on the left side of the equation is $1 - (p + q + r)$.

Under this individual equity axiom, the utility of the left-hand side is $a_1p + a_2q + 2r$. The utility of the right-hand side is $a_1q + a_2p + 2r$. They are equal, so

$$a_1p + a_2q + 2r = a_1q + a_2p + 2r.$$

Subtracting $2r$ from both sides,

$$a_1p + a_2q = a_1q + a_2p.$$

Rearranging, we get

$$a_1(p - q) = a_2(p - q),$$

and thus

$$a_1 = a_2.$$

Ex Ante Equity

Ex ante equity can be seen “before the fact” of a risk event being resolved. A person who prefers *ex ante* equity will choose an equal distribution of risk, where risk is defined by the probability of an individual becoming a fatality, over an unequal distribution.

Consider the scenario below.

Ex Ante Equity Scenario

Alternative A: 50% chance that Person 1 lives, Person 2 dies

50% chance that Person 1 dies, Person 2 lives.

Alternative B: Person 1 lives,
Person 2 dies.

In Alternative B, one person dies for sure, and we know that it will be person 2. In Alternative A, one person dies for sure, also. So, if a societal decision maker wishes to use a von Neumann–Morgenstern utility function defined over number of fatalities (only), then the model will be indifferent between the two alternatives.

Before the uncertainty in Alternative A is resolved, each person has an equal 0.5 chance of death, so they share in facing the risk. Alternative B has an unequal distribution, with person 1 having a probability of 0 of death and person 2 having a probability of 1. A decision maker who prefers Alternative A, because it “is fairer since each person has an equal chance of surviving,” is demonstrating a preference for *ex ante* equity.

This seemingly reasonable assumption has been debated in the literature and

has caused some to conclude that the decision analytic approach (when considering only the number of fatalities rather than the distribution of risk) cannot satisfactorily address this equity issue; see Broome [6].

Risk-Sharing Equity. To generalize the notion of *ex ante* equity from the scenario above, recall Fishburn’s notation introduced in the section titled “Individual Equity,” where p and q refer to the probabilities:

p chance that (Person 1 lives, Person 2 dies)

q chance that (Person 1 dies, Person 2 lives).

According to Fishburn’s [7] *risk-sharing equity axiom E2*,

if $p + q = p^* + q^*$ and $|p - q| < |p^* - q^*|$ then

$$u(p, q, r, \#) > u(p^*, q^*, r, \#).$$

In the scenario above, $p = q = 0.5$ in Alternative A, and in Alternative B we have $p^* = 1$ and $q^* = 0$, so according to the risk-sharing equity axiom, $u(A) > u(B)$.

Independence Risk Equity. Next, we consider a preference for equal *independent* probabilities of death. The *independent risk equity axiom E3* by Fishburn [7] considers the two person’s *ex ante* independent probabilities of living (rather than dying), and states it is better if the probabilities are closer together (rather than farther apart). Let α be the probability that person 1 lives and β be the probability that person 2 lives. Each can live alone or with the other person.

Consider Option 1 with the following probabilities and outcomes:

$\alpha(1 - \beta)$ p chance that Person 1 lives,

Person 2 dies,

$(1 - \alpha)\beta$ q chance that Person 1 dies,

Person 2 lives,
 $\alpha\beta$ r chance that Person 1 lives,
 Person 2 lives, i.e. both live, or
 $\#$ $1 - (p + q + r)$ chance that
 Person 1 dies, Person 2 dies, i.e.
 both die.

Person 1 can live alone with the probability $\alpha(1 - \beta)$, or can live with Person 2 with the probability $\alpha\beta$. So, person 1 has a probability of living $= \alpha = \alpha(1 - \beta) + \alpha\beta$ and Person 2 has a β probability of living, where $\beta = (1 - \alpha)\beta + \alpha\beta$.

Option 2 has the same structure, but α and β are replaced with α^* and β^* .

Independence Risk Equity Axiom.

If $\alpha + \beta = \alpha^* + \beta^*$ and
 $|\alpha - \beta| < |\alpha^* - \beta^*|$, then
 $u(\text{Option 1}) = u(\alpha(1 - \beta), (1 - \alpha)\beta, \alpha\beta, \#)$
 $> u(\text{Option 2}) =$
 $u(\alpha^*(1 - \beta^*), (1 - \alpha^*)\beta^*, \alpha^*\beta^*, \#).$

So, a more even division of the unconditional probabilities of living is preferred. This is the same as Keeney's [5] risk equity assumption under independence between the unconditional events "1 dies" and "2 dies." Under this axiom, $u(\text{Person 1 lives, Person 2 dies}) = a_1 = u(\text{Person 1 dies, Person 2 lives}) = a_2 < 1$.

Consider the scenario below given by Keller and Sarin [9] to Americans and by Bian and Keller [10] to Chinese.

Serum Distribution Scenario. There are 100 islanders who are susceptible to a specific fatal disease which has recently appeared on the mainland. Scientists have identified a kind of serum which has the potential of protecting people from contracting the disease. *Unfortunately, there is not enough serum available to give all the susceptible islanders a high enough dose to successfully prevent the disease.* Action must be taken immediately to protect the public health.

All susceptible people must be injected with the serum within 24 hours, or each will have a 15% chance of contracting the disease and eventually dying. There is no time to acquire more serum. There are only 3000 milligrams of the serum available. As the public health officer, it is your job to choose between the following options. Circle your choice.

- A. Give the same low dose of 30 milligrams of serum to all 100 susceptible islanders. 50 of those susceptible are northerners, 50 are southerners. Each susceptible person will have an independent 10% chance of dying. The expected number of deaths is 10. (Considered more fair and chosen by most Americans and Chinese)
- B. Divide up the available serum among the 50 northerners who are susceptible to the disease. Thus, these people will receive a higher 60 milligram dose. Each of the 50 will now have an independent 5% chance of dying. Since the 50 susceptible southerners will receive none of the serum, each will still have a 15% chance of dying by contracting this disease. The expected number of deaths is 10.

Preference for equal independent probabilities of death in option A reveals a preference for independence risk equity. It is clear from the survey (in which half the subjects reported which option was fairer and the other half reported their chosen action) that the subjects' preference for option A has resulted from it being a fairer choice; however, technically speaking, such a choice can be explained by assuming that their utility functions defined over number of fatalities are risk prone. See the section titled "Catastrophe Avoidance" for a discussion of utility function shapes.

Measure of Ex Ante Equity Φ . There are different ways to measure *ex ante* equity quantitatively. A specific measure of *ex ante* equity Φ is one that penalizes unevenness across groups in terms of the average probability of death $\bar{p}_i$ for a person in group i , $i = 1$ to m [9]. Presuming there are roughly equal numbers of people in each group, a special

form for Φ is defined by

$$\Phi = - \sum_{i=1}^m |\bar{p}_i - \bar{p}|,$$

where the average of the probabilities of death for the m groups is $\bar{p} = \sum_{i=1}^m \bar{p}_i / m$. For the simple *ex ante* equity scenario above at the beginning of the section titled “*Ex Ante Equity*,” there are two groups, each having one person in it.

For Alternative A,

$$\Phi = -(|0.5 - 0.5| + |0.5 - 0.5|) = 0,$$

For Alternative B,

$$\Phi = -(|1 - 0.5| + |0 - 0.5|) = -1.$$

So, Alternative A has the higher (and presumably better) *ex ante* equity. See the section titled “Fair-Risk Model, Incorporating *Ex Post* and *Ex Ante* Equity Preferences” for a societal utility function which includes Φ .

For another example of preference for *ex ante* equity, see the rescuer at risk scenario in ***Fairness and Equity in Societal Decision Analysis***.

Ex Post Equity

A person who prefers *ex post* equity will choose an equal *ex post* distribution of final outcomes for the affected people, instead of an unequal distribution [7].

Consider the scenario below. First note that, in terms of *ex ante* equity, both alternatives are equal, since both lead to an *ex ante* probability of 0.5 that Person 1 dies and 0.5 that Person 2 dies. Thus, a decision maker cannot distinguish between the two alternatives in terms of *ex ante* equity. Now examine the alternatives below in terms of *ex post* equity.

Ex Post Equity Scenario

Alternative C: 50% chance that Person 1 lives, Person 2 lives
50% chance that Person 1 dies, Person 2 dies

Alternative A: 50% chance that Person 1 lives, Person 2 dies
50% chance that Person 1 dies, Person 2 lives

After the uncertainty is resolved in Alternative C, the *ex post* outcome is either both people will be dead or both people will be alive. In Alternative A, the *ex post* outcome will be that one person is alive and one is dead. So, Alternative C will be chosen by a person preferring *ex post* equity.

Common-Fate Equity. Common-fate equity is a typical kind of *ex post* equity. Note that in Alternative C above, after the fact of the risk event occurring (or not) the two people will share a common fate (either both living or both dying), no matter what happens. In Alternative A, they will have different fates, no matter what happens. In many situations, people will prefer to share a common fate. But, in some situations, such as when top executives of a company or parents of young children take air flights, they may take different flights to avoid the common fate of dying in the same airplane crash. In both of these situations, they are thinking of their responsibilities to their company or family.

Fishburn’s [7] *common-fate equity* axiom E4 states

$$u(p - \delta, q - \delta, r + \delta, \#) > u(p, q, r, \#).$$

In this axiom, it is an improvement to move the probability up that the two people share common fates (which occurs in consequence 3: both living, and consequence 4: both dying) and move the probability down that they have unequal fates (in consequence 1: only Person 1 lives and consequence 2: only Person 2 lives). Under this axiom, $u(\text{Person 1 lives, Person 2 dies}) + u(\text{Person 1 dies, Person 2 lives}) = a_1 + a_2 < 2$.

Gajdos *et al.* [11] present a new method for modeling preference for (or against) what they call “shared destinies,” which weakens a necessary and sufficient condition by Fishburn and Straffin [12] for two societal risk distributions to be judged to be indifferent whenever their associated distributions

of risk of death for individuals and for the number of fatalities are the same.

For an example of common-fate equity, see the miner location scenario discussed in Keller and Sarin [9]; see also Section 3 in ***Impossibility Theorems and Voting Paradoxes in Collective Choice Theory***.

Also, in the section titled “Catastrophe Avoidance,” Alternative D has common-fate equity, with either all 100 dying or all 100 living.

Common-Fate Independence. Fishburn’s [7] *common-fate independence* axiom E5 states

$$\begin{aligned} \text{If } p + r = p^* + r^* \text{ and } q + r = q^* + r^*, \\ \text{then } u(p, q, r, \#) = u(p^*, q^*, r^*, \#). \end{aligned}$$

In this axiom, it does not matter how a person dies, as long as the probability of dying remains the same. As long as a person’s probability of dying is constant, the probability can be split in any division between dying alone and dying together. This is a different kind of *ex post* equity. Under this axiom, $u(\text{Person 1 lives, Person 2 dies}) + u(\text{Person 1 dies, Person 2 lives}) = a_1 + a_2 = 2$.

Ex Post Equity Measure θ . As one example of an *ex post* equity measure, Keller and Sarin [9] suggest the following equity measure, θ , which depends on the distribution of the number of fatalities among the m groups. Suppose there are n_i fatalities in group i , $i = 1$ to m . Then

$$\theta = \sum_{n_m=0}^{N_m} \sum_{n_{m-1}=0}^{N_{m-1}} \dots \sum_{n_1=0}^{N_1} \pi(n_1, n_2, \dots, n_m),$$

where π is the joint probability mass function that can be computed from the estimates of risks to members in each group. N_i is the maximum possible number of fatalities in group i , $i = 1$ to m .

If $\bar{n}$ is the expected number of fatalities per group and each group experiences exactly $\bar{n}$ fatalities, there is no *ex post* inequity, from the perspective of a comparison across groups. So, any deviation from $\bar{n}$ is an

indication of *ex post* inequity, especially when the size of the population in each group is approximately the same or is substantially larger than the number of fatalities actually experienced. In this case, Keller and Sarin [9] define the *ex post* equity of a specified number of fatalities n_i in each group i as

$$\theta(n_1, n_2, \dots, n_m) = - \sum_{i=1}^m (n_i - \bar{n})^2.$$

For the simple *ex post* equity scenario above at the beginning of the section titled “*Ex Post* Equity,” there are two groups ($i = 1$ and 2), each having one person in it. The data to compute θ are organized in the following table for a generic policy alternative.

In each row in the table, multiply the probability from column 1 times $\theta(n_1, n_2)$ in the last column, then sum up the four products to get the overall *ex post* equity measure θ .

In the *ex post* equity scenario,

Alternative C has $p = 0$, $q = 0$, $r = 0.5$ and $\# = 0.5$, so $\theta = 0.5(0) + 0.5(0) = 0$.

Alternative A has $p = 0.5$, $q = 0.5$, $r = 0$ and $\# = 0$, so $\theta = 0.5(-0.5) + 0.5(-0.5) = -0.5$.

Higher numbers indicate better performance in terms of *ex post* equity, so Alternative C has the best *ex post* equity, with $\theta = 0$. One can interpret this as zero inequity. More negative numbers show greater *ex post* inequity. See the section below on fair-risk models for a societal utility function which includes θ .

Catastrophe Avoidance

Merely calculating expected number of lives lost and choosing protective actions that minimize the number of expected lives lost can lead to choices that might not be agreed upon by members of society. By observation of the nightly TV news we see that the public often reacts more to disasters when 100 people are lost all at once rather than 100 less newsworthy smaller events when one person at a time dies. It is as if the disutility of 100 deaths at once is greater than 100 times the disutility of 1 death.

Probability of Specific Number of Deaths in Group 1 and Group 2 $\pi(n_1, n_2)$	Group 1 Fate of Person 1	Number of Fatalities in Group 1 n_1	Group 2 Fate of Person 2	Number of Fatalities in Group 2 n_2	Average Number of Fatalities $\bar{n}$	$\theta(n_1, n_2)$
p chance	Person 1 lives	0	Person 2 dies	1	0.5	$-((0 - 0.5)^2 + (1 - 0.5)^2) = -0.5$
q chance	Person 1 dies	1	Person 2 lives	0	0.5	$-((1 - 0.5)^2 + (0 - 0.5)^2) = -0.5$
r chance	Person 1 lives	0	Person 2 lives	0	0	$-((0 - 0)^2 + (0 - 0)^2) = 0$
$1 - (p + q + r) = \#$ chance	Person 1 dies	1	Person 2 dies	1	1	$-((1 - 1)^2 + (1 - 1)^2) = 0$

According to Keeney's [5] catastrophe-avoidance condition and Fishburn's [7] *catastrophe-avoidance preference axiom E6*,

$$u(p, q, 1 - p - q, 0) > u(0, 0, 1 - (p + q)/2, \#).$$

In this axiom, it is better for at least one person to survive (just Person 1 in consequence 1 or just Person 2 in consequence 2) than to have both die when the expected number of deaths is equal. Under this axiom, $u(\text{Person 1 lives, Person 2 dies}) = a_1 > 1$ and $u(\text{Person 1 dies, Person 2 lives}) = a_2 > 1$.

Consider the scenario below given by Keller and Sarin [9] to Americans and by Bian and Keller [10] to Chinese. In this scenario, both alternatives have an expected loss of one life, so in terms of expected number of fatalities, they are equal.

Serum-Producing Scenario.

One hundred islanders were born highly susceptible to contracting a fatal disease. Recently, it was discovered that the presence of a naturally occurring noxious gas led to this condition and the gas has been eradicated. However, there is still some chance of the islanders contracting the disease and thus

dying. You could decide to give an injection to all 100 islanders. This injection will prevent everyone from contracting the disease. However, the serum for the injection can only be obtained from the blood of a person who has artificially been made to contract the fatal disease. The serum cannot be obtained from a person who has naturally contracted the disease, so you cannot just wait to see if one person contracts the disease and then make the serum from the sick person's blood. If one islander is sacrificed by being made to contract the disease, enough serum will be obtained to eliminate the risk of death to the remaining 99 islanders. If nothing is done, there is a 1% chance of an epidemic breaking out in which all 100 islanders will contract the disease and thus die. There is a 99% chance that no epidemic will break out, so all 100 islanders will live.

The two options are summarized below. Circle your choice/the option that is fairer.

Alternative D: Do nothing, and thus take a 1% chance of all 100 islanders dying (*Considered fairer by most Americans and Chinese, and chosen by most Americans*).

Alternative E: Sacrifice one islander (*Chosen by most Chinese*).

Alternative D was seen as fairer by most Chinese and Americans. It was chosen as an action by most Americans. It has the chance of the catastrophe of all 100 dying, yet each person has an equal 1% chance of dying. Thus, there is *ex ante* equity and *ex post* equity. There is also common-fate equity, since in one outcome all 100 live and in the other outcome all 100 die.¹

Alternative E avoids any risk of catastrophe, but involves one specific person dying for sure. Most Chinese chose Alternative E, so they preferred *catastrophe avoidance*. It may be that the Chinese cultural value of collectivism led Chinese to protect the 100 person group from all dying, even if one individual had to be sacrificed. In contrast, more Americans may have been led by the American cultural value of individualism to choose Alternative D.

Keeney [4,5] shows that a preference for more equitable distributions of risk, like in the “Do nothing” Alternative D, implies a risk-prone attitude and that catastrophe avoidance, like in the “Sacrifice 1 islander” Alternative E, reveals a risk-averse attitude. Table 1 provides examples of utility functions over number of fatalities which are risk prone, risk neutral, or risk averse. The scale is from 0 to 1, but can be rescaled from -1 to 0, if decision makers prefer to use negative numbers for outcomes of deaths. (See the section titled “Utility Function Demonstrating a Preference for *Ex Post* Equity” for another risk-prone utility function.)

Envy-Free Allocation

Imagine you give some cookies to two children. When one child whines “That’s not fair,” what is meant by this complaint? It could mean that she *envies* the cookie allocation given to the other child, in comparison to her own cookie allocation.

The concept of an *envy-free allocation* means that neither child wants to switch his allocation with the other child.

An envy-free cookie allocation might be attained by following a process where the first child divides the cookies and the second child chooses which of two piles of cookies to take, leaving the rejected pile for the child who divided them.

Envy-Free Axiom.

The chosen allocation should be envy free. An allocation (of risks and/or benefits) between two people is envy free if neither person would want to switch his/her allocation with the other person.

Keller and Sarin [9] discuss the idea of an envy-free allocation of risks and benefits as a way to resolve controversial facility siting problems. See the section titled “Envy-Free Allocation Model.”

DECISION MODELS CONTAINING EQUITY MEASURES

One purpose of identifying equity axioms is to examine what equity principles are satisfied in different existing decision models. A related purpose is to build a decision model based upon the desired set of equity axioms. This section provides a few examples of decision models incorporating a variety of equity preferences and applications. For more models see papers cited earlier and Refs 15–29 for additional references on societal equity.

Utility Function Demonstrating a Preference for *Ex Post* Equity

If societal decision makers prefer more equitable distributions of *ex post* risk, then they may choose to evaluate each individual at risk identically to all others [2,4]. A utility function over the number of fatalities can sufficiently summarize preference for this concept of *ex post* equity of public risk. One specific utility function form examined in

¹This scenario’s context is a modification of one presented in Hammerton *et al.* [13]. Fischhoff [14] used the same probabilities and outcomes to illustrate framing effects and only 29% chose the sure-loss option E. Thus, subjects generally preferred the more equitable option D in a civil defense context also.

Table 1. Examples of Utility Functions Over Number of Fatalities

Utility in Serum-Producing Scenario	Risk Prone: Prefer D (Do Nothing) over E (Sacrifice One Islander)	Risk Neutral: Indifferent between D (Do Nothing) and E (Sacrifice One Islander)	Risk Averse: Prefer E (Sacrifice One Islander) Over D (Do Nothing)
Utility of 0 deaths	1.000	1.000	1.000
Utility of 1 death	0.950	0.990	0.995
Utility of 100 deaths	0.000	0.000	0.000

Keeney [4] is a constantly risk-prone utility function $u(y)$, over the number of fatalities y :

$$u(y) = (1/d)[(1 - d)^y - 1], 0 < d < 1, \\ y = 0, 1, 2, \dots, N,$$

where $u(0 \text{ fatalities}) = 0$ and $u(1 \text{ fatality}) = -1$ to set the origin and scale. Figure 1 below shows the utility over number of fatalities y when the curvature parameter $d = 0.01$. In this convex utility curve with $d = 0.01$, $u(1) = -1$, $u(10 \text{ fatalities}) = -9.56$, $u(20 \text{ fatalities}) = -18.21$, $u(100 \text{ fatalities}) = -64.40$, and $u(200 \text{ fatalities}) = -86.60$. For smaller values of d , the curve is more linear. For $d = 0.0000001$, the utility curve is nearly linear. Also since $\lim_{y \rightarrow +\infty} u(y) = -1/d$, the negative reciprocal of d can be interpreted as the lower bound on the utility due to the societal impact of a tragedy where y is large. Alternatively, d can also be interpreted as the ratio of the societal utility of the first involuntary risk fatality to that of a large tragedy.

To include preference over fatalities, the utility function should be monotonically decreasing since fewer fatalities are always preferred; To include preference for *ex post* equity, the utility function should be risk prone (convex) since a lottery with an expected number of fatalities should be preferred to a sure consequence with the same fatalities which has less spread over society members. The utility function above is both monotonically decreasing and convex. Thus the utility function above addresses both attitudes toward fatalities and *ex post* equity without separating them into individual components.

Fair-Risk Model, Incorporating *Ex Post* and *Ex Ante* Equity Preferences

Keller and Sarin [9] present a simple weighted additive model that includes the number of fatalities, *ex ante* equity of the distribution of the risks, and the *ex post* equity of final consequences. (Keeney and Winkler [2] propose a similar weighted additive structure, in their Equation (3).) Suppose the N_i members in each of m groups, indexed by i , have an independent probability p_i of becoming a fatality. The *fair-risk model* is

$$K_Y U_Y(y) + K_\theta \theta + K_\Phi \Phi,$$

where U_Y is the utility function defined over number of fatalities y , θ is the *ex post* equity measure defined in the respective section, Φ is the *ex ante* equity measure defined in its respective section, and K_Y, K_θ , and K_Φ are scaling constants that reflect trade-offs among the three attributes. A simple utility function U_Y for total number of fatalities is the negative of the expected number of fatalities.

Examination of Antarctica Operations in Terms of Equity to Different Groups

Broder and Keller [17] provide examples of equity measures applied to Antarctica operations. They created two stylized scenarios, based on interviews with US Antarctica operations managers at the US National Science Foundation and reviews of planning documents. In scenario 1, the *status quo* situation was represented, with different fatality risks from a tourist airplane crash or a fatal emergency in Antarctica operations for 3000 tourists, 50 rescue workers, and 950

Figure 1. Utility function over number of fatalities when $d = 0.01$.

other Antarctica workers. In scenario 2, a streamlining plan then under consideration was represented in a stylized example where the other Antarctic workers were decreased to 900, and the probabilities and numbers of deaths in groups changed a bit. They then numerically calculated the following equity measures, based on formulae proposed in Fishburn and Sarin [28]:

- individual risk (*ex ante*) inequity;
- group risk (*ex post*) inequity;
 - intergroup inequity (nonuniformity of expected fatality rates across groups);
 - within-group risk inequity;
 - total group risk inequity, that is, combining intergroup and within-group inequity measures,
 - social outcome inequity, assuming common-fate preferences;
- dispersive inequity, for example, risks to scientists versus support staff compared with risks to governmental versus nongovernmental workers, when there are overlapping memberships in these groups (since there are governmental scientists, nongovernmental scientists, governmental support staff, and non-governmental support staff).

Envy-Free Allocation Model

Keller and Sarin [9] presented the following envy-free risk benefit model, which incorporates the concept of an envy-free allocation, as described in the corresponding section. This model also includes information on both the risks and the benefits received by each party. For scenarios involving risks and benefits, see Keller and Sarin's [9] scenario 6 and the scenarios in Keller and Sarin [15].

The model argues that an allocation of benefits b_i and risks r_i to each group i expressed as $(b_1, r_1; b_2, r_2; \dots; b_m, r_m)$ is fair if $u_i(b_i, r_i) \geq u_i(b_j, r_j)$ for $i = 1$ to m , $j = 1$ to m . Then if we assume that a decision maker has a utility function u_D , which is defined over the utility functions u_i of each of the $i = 1$ to m groups, the following mathematical program will give you the fair allocation:

Envy-Free Risk-Benefit Model

Maximize $u_D(u_1, u_2, \dots, u_m)$

Subject to

$$u_i(b_i, r_i) \geq u_i(b_j, r_j), i = 1 \text{ to } m, \\ j = 1 \text{ to } m$$

(envy-free allocations)

$$\sum_{i=1}^m b_i = 1 \quad (\text{all benefits allocated})$$

$$\sum_{i=1}^m r_i = 1 \quad (\text{all risks allocated})$$

$$b_i, r_i \geq 0, i = 1 \text{ to } m$$

(nonnegative variables).

In the above model u_D can be regarded as a social welfare function. u_D increases in group i 's utility u_i . Group i 's utility u_i increases in the benefits b_i and decreases in the risks r_i .

SUMMARY

This article has provided an introduction to a number of *ex ante* and *ex post* equity concepts. When guiding societal policy making, such concepts will often be part of the discussion. They can be dealt with qualitatively in policy discussions, or be formally incorporated into preference models for guiding decision making. Some examples of societal utility function models are discussed in the section titled "Decision Models Containing Equity Measures." See Refs 15–29 for additional references on societal equity, and the article titled ***Fairness and Equity in Societal Decision Analysis***.

BRIEF HISTORICAL NOTES

Two decades ago, a technical report from a high-performance computing group suggested that we were at a turning point in the application of mathematical programming solutions to challenging optimization problems [1]. This same manuscript also introduced the denomination of “*memetic algorithms*” (MAs). The conclusions obtained were based on the computational experience obtained with Norman and Moscato’s first MA [2]. The results were obtained with the first computer code implemented by Norman in November 1988, who skillfully ported it, in just a matter of days, to two different types of parallel computers. This first program was then thoroughly tested and examined by Moscato during most of 1989 using different variants of the basic initial MA scheme on a number of instances of the traveling salesman problem (TSP) [1]. That technical report presented a qualitative analysis of other hybrid metaheuristics published at the time. It was suggested that MAs were the natural unifying scheme, and the report also predicted the usefulness of this approach and theorized on the reasons for its success.

A common misconception remains 20 years later; some researchers still believe

that MAs evolved from hybrid genetic algorithms (GAs), a new (or at least incipient in 1988) type of strategy for combinatorial and nonlinear optimization. This is certainly not true. MAs actually evolved from the principle that the pragmatic use of different problem-specific algorithmic strategies for a given computational search problem can be synergistically used. The particular target hardware for these algorithms was heterogeneously distributed computing systems and concurrent/parallel computer systems. Moscato recognized the *computer game tournaments* [2,3] used to study *the evolution of cooperation* as his influence [4,5]. As a consequence, from the beginning, MAs were defined as a *competitive and cooperative approach for complex optimization search* [6], where software agents compete for CPU time and can achieve *superlinear speedup* [7]. From the very beginning, the emphasis was on combinatorial optimization problems, as it was perceived that a steady progress on algorithmic solvers for well-known test case scenarios, like those provided by the traveling salesman or the quadratic assignment problem instances, would lead to a clear recognition of the power of these new hybrid algorithms.

By 1989, algorithmic developers in the field of evolutionary computation were subjected to unnecessary restrictions by the *genetic algorithm dogma*, and were constrained to publishing only methodologies that were highly linked to biological evolution. Moscato then proposed that, perhaps, ideas from *cultural evolution* could be a more compelling way of introducing the liberating quest of MAs. In turn, it seemed closer to the discussion of the evolutionary dynamics cultural processes, in which the correct utilization of problem domain knowledge is of paramount importance, which is also one of the key elements of MAs. The term *memetic*, derived from Richard Dawkins’ neologism *meme*, was the perfect match [7]. Since we have *hybridization* of algorithmic techniques as a key ingredient

of MAs, it was not entirely unexpected that at the beginning of the 1990s there was a surge of evolutionary algorithms that used this term, with Lawrence Davis being one of the most stoic supporters of the necessary changes required to be competitive with state-of-the-art algorithmics [8–10]. It was not Moscato's purpose to eliminate an existing dogma by generating a new one. Instead, he aimed at noting more comprehensive forms of evolutionary systems that gain information by creation and destruction processes but employ long periods of individual optimization of designs.

In the early 1990s, researchers who were working on MAs, if they were willing to publish their results, most likely needed to show that their methods were improving existing state-of-the-art heuristics and metaheuristics. Consequently, a benchmark was to show that the cooperative and competitive aspects of their hybrid strategies were producing better results than when acting individually. This resulted in a large number of papers where the MAs were presented as *hybrid evolutionary algorithms*, *hybrid genetic algorithms*, *hybrid metaheuristics*, *genetic local search*, and so on. Reviewers required that these hybrids should outperform both the basic population-based strategies for optimization as well as known metaheuristics like *simulated annealing* (SA) or *tabu search* (TS). This has resulted, during the next 20 years, in a stream of publications that combine these methods as individual optimizers for each agent with population-based techniques, resulting in very robust optimization methods.

MAs have pioneered and championed hybridization of algorithmic techniques, and anticipated many existing methodologies in practice today, which are converging toward this paradigm. We note that the early references to MAs [1] already make use of individual search optimization techniques, which may be different for each agent, use other metaheuristics (i.e., SA, TS and some forms of *variable neighborhood search*), and control the solution population to avoid premature loss of diversity via mechanisms that employ a certain structure of the population (e.g., toroidal [1] and tree [7]).

MAs were also the first metaheuristic that clearly championed the need and relevance of using mathematically literate computing techniques, incorporating *anytime algorithms*, *heuristics*, *approximation algorithms*, *local search techniques*, and *truncated anytime complete algorithms*, with population-based approaches. With a new generation of researchers, after having proved the case, and also due to innovations in the area of exact algorithms, new MAs that include powerful adaptive systems are being developed, while retaining a preference for the design of *parameter-free* MAs, which are very robust, easily implementable, computational solutions for challenging problems.

BASIC ELEMENTS OF A MEMETIC ALGORITHM

All MAs are characterized by the use of (i) a population of agents that use search/optimization methods over a set of solutions (instead of a single optimizing agent); (ii) at least one form of a *competitive* mechanism that produces some sort of selective pressure, not driven entirely by the objective function value of the solutions already found; and (iii) at least one type of *cooperative* procedure that allows information exchange between agents. The search/optimization processes used by each agent do not necessarily need to be the same. It is also not necessary that an individual agent should have “exhausted” its exploration to be ready to recombine solutions. These types of strategies were already presented in the earliest implementations of MAs and are not a novel concept [1]. Another aspect normally present in MAs is that the “wall-clock” time used during exploration by individual agents tends to be much greater than the time employed during the exchange of information. As such, MAs have gained popularity as being ideal for MIMD parallel computer systems. It is increasingly the case that MAs are being used as a metaheuristic template and are becoming the focal point of convergence of several metaheuristic techniques, where these principles of cooperation and competition are used interspersed in many ways.

Solution, Representation, and Fitness/Guiding Functions

One of the first elements highlighted by Moscato [1] as a key for the development of MAs is the choice of a suitable *representation* of solutions of the computational problem at hand. Moscato insisted on the key role that the *correlation of local optima* had on the performance of a MA [1,11], and used the Kauffman's NK-landscapes, the TSP, the quadratic assignment problem, and the problem of finding the optimal conformation of proteins as key examples where the correlation of local optima is in some way evident. In other cases, it can be somewhat enforced by the choice of a particular "*configuration space*" [1,11]. Consequently, we need to define these terms more formally. Readers can then reflect on how to approach a new problem with MAs by choosing a proper configuration space. We note, however, that we have more or less simplified the discussion in what follows, as different agents could be using different configuration spaces, yet they can be exchanging information about the solutions found using some common specification.

In several MAs, it is customary to use a single search space S and we refer to the elements $s \in S$ of this space as *configurations*. The search in this *configuration space* is linked to a search on associated sets that represent solutions of the problem at hand, and consequently some definitions are necessary to formalize these concepts. We assume here that the task is to solve a computational problem P , which has a domain set of *instances* denoted I_P (the "inputs"). For each instance $x \in I_P$, we have an associated set called $\text{solp}(x)$, which represents the *feasible* solutions for problem P given instance x (the "output" we need to compute). The set $\text{solp}(x)$ is also known as the set of *acceptable* or *valid* solutions. Generating these valid solutions is generally not hard (formally, computationally tractable for many problems of interest). Our algorithm must, given an instance $x \in I_P$, return at least one element y from a set $\text{ansp}(x) \supseteq \text{solp}(x)$, that is, a potential (hopefully feasible) solution to the problem. Computational problems can then be classified as follows: *decision* problems (the task

is to determine whether the set $\text{solp}(x)$ is *empty or not*); *satisfaction/search problems* (the task is to find *one* solution $y \in \text{solp}(x)$); *enumeration* problems (the task is to find *all* solutions in $\text{solp}(x)$); *counting* problems (the task is to find *how many* solutions exist in $\text{solp}(x)$); and *optimization* problems (the task is to find a solution in $\text{solp}(x)$, maximizing or minimizing a given function). The latter is the group for which MAs have been mostly used as heuristic *anytime* algorithms. There are, however, MAs that guarantee to deliver the optimal solution, and, in that case, following the standard use of the term in artificial intelligence, we call them *complete MAs*.

An optimization problem is considered *solved* by an MA if it guarantees that it always finds a certain feasible solution $y \in \text{solp}(x)$ or gives an indication that no such feasible solution exists. A Boolean *feasibility* function $\text{feasiblep}(x, y)$ may sometimes be required. The function reports TRUE whether a given solution $y \in \text{ansp}(x)$ is acceptable for an instance $x \in I_P$ of a computational problem P , that is, checking if $y \in \text{solp}(x)$. An MA is said to *solve problem* P if it can fulfill this condition for any given instance $x \in I_P$. There is no doubt that this is a broad definition, hence a more restrictive characterization for our problems of interest is necessary. This characterization is provided by restricting ourselves to *combinatorial optimization* problems, in which the cardinality of $\text{solp}(x)$ is finite for each instance $x \in I_P$, and—as for any optimization problem—a partial order $<_P$ is defined over solutions, so that preferences among them can be established. This partial order is typically defined by means of an objective function that numerically quantifies the quality of a solution (see also the section titled "Multiobjective Memetic Algorithms" for a generalization of this scenario). An instance $x \in I_P$ of a combinatorial optimization problem P is solved by finding the best solution $y^* \in \text{solp}(x)$, that is, finding a solution y^* such that no other solution $y <_P y^*$ exists if $\text{solp}(x)$ is not empty. Note that the optimal solution may not be unique.

We now need to define what a *valid search space* is. Let $S_P(x)$ be a set defined for problem

P whose elements have the following properties: (i) each element $s \in S_P(x)$ represents an answer in $\text{ansp}(x)$ and (ii) *at least one optimal* element y^* of $\text{solp}(x)$ is represented by one element in $S_P(x)$. The elements of $S_P(x)$ are named *configurations* (note that some configurations in the search space explored by MAs may actually correspond to infeasible solutions). For simplicity, we just write S to refer to $S_P(x)$ when x and P are clear from the context. People using biologically inspired metaphors like to call $S_P(x)$ the *genotype space* and $\text{ansp}(x)$ the *phenotype space*, hence we appropriately refer to $g : S_P(x) \rightarrow \text{ansp}(x)$ as the *growth function*.

Designers of MAs generally take inspired advantages of these arbitrary mathematical constructions and, given a problem P , the set $\text{solp}(x)$ is not necessarily the same as $\text{ansp}(x)$. For instance, the use of a *growth function* $g : S_P(x) \rightarrow \text{ansp}(x)$ would allow that a known and useful greedy constructive algorithm may be deterministically generating a solution from a configuration in $S_P(x)$. In addition, each agent in the population may be using a different $S_P(x)$, and it is common to have MAs in which each agent is concurrently optimizing a pool of configurations, with a set of different algorithmic techniques. It is part of the craftsmanship of MAs to be well versed in different algorithmic techniques in order to produce hybrids that bring the best elements among them and synergize to achieve better results in reduced times, exploiting the possibility of *superlinear speed up*, thus making the approach a practical choice. Almost invariably, we have noticed that *correlation of local optima* [1] is always present in good MA implementations [1,11–13].

Individual, Local, and Population-Based Processes

Local search algorithms maintain a single configuration at a time; the maintenance of $k \geq 2$ configurations is an obvious generalization. We call *population-based* search algorithms those search techniques that use multiple concurrent configurations during the search process. Most MAs, either explicitly or implicitly, use a population-based search [11].

Given a certain search space $S = S_P(x)$, an objective function, and a particular search engine determining which solutions are reachable from which other solutions, the search process can be adequately modeled as traversing a so-called *fitness landscape* [13–15]. The latter aspect, namely, the connectivity of the search space largely determines the dynamics of the search algorithm. In local search, a widely used method in MAs, these connectedness relationships are dependent on a *neighborhood function* $N_P(s, x) : S \rightarrow 2^S$. This function assigns to each element $s \in S$ a set $N(s) \subseteq S$ of neighboring configurations of s . The set $N_P(s, x)$ is called the *neighborhood* of s and each element in $N_P(s, x)$ is called a *neighbor* of s . In local search agents, we iteratively explore $N_P(s, x)$, starting with a configuration $s_0 \in S$ (generated at random or constructed by some other algorithm) until a termination criterion is met (realization of a number of iterations, no improvement in the last m iterations, the probability of being at a local optimum, etc. [16]). In MAs, the generation of these new configurations $s_0 \in S$ is due to processes that combine features present in other configurations, by *recombination* processes (see section titled “Recombination and Mutation”). Other types of exact algorithms are used for individual optimization and recombination algorithms. We describe in the section titled “Adaptive Memetic Algorithms,” some of the exact methods that are currently being used. It is not a design requirement of MAs that recombination should proceed only if the solutions to be recombined are local optima; in fact, even the first MAs explicitly avoided this unnecessary restriction [1,11].

Random diversification of the search process is necessary, and MAs employ a variety of procedures (called *mutations* in the context of GAs) to achieve this diversification. These randomizations may be simple or complex “chain of transitions” [17]. Early on, it was clear that even a finite size population would lose diversity, and *restart* mechanisms were proposed in MAs to generate new configurations, iterating to find even better regions of configuration space.

Another method to increase diversification is to introduce a *population structure*

[1,7,18–20], which in turn prevents some recombinations from taking place. Moscato and Norman [6] introduced these structures in their first MA. This methodology has been used by several authors [5,9], but it is yet underexploited in its full potential.

Recombination and Mutation

Recombination operators are algorithms that allow the generation of new restart configurations for the individual search processes in MAs. In MAs, “recombination” is not linked to a particular “biological” metaphor, that is, it allows the use of “multiparents” ($k > 2$), the use of previously generated solutions, constructive algorithms, and so on. The use of clever recombination algorithms, which synergize with the individual search optimizers, allows a more efficient exploration of fitness landscape and it is part of the design of good MA implementations. Recombination can be defined as a process in which a set S_{par} of n configurations (informally referred to as “parents”) is manipulated to create a set S_{desc} of new configurations. The creation of these new configurations involves the identification and combination of features extracted from the parents. Important properties of recombination operators are *respect* (offspring carry features common to both parents), *assortment* (offspring can potentially carry any combination of compatible features from the parents), and *transmission* (offspring exclusively include

features carried by any of the parents) [21,22]. A recombination operator is said to be *blind* if it has no other input than S_{par} , that is, it does not use any information from the problem instance. This definition is certainly very restrictive, and hence is sometimes relaxed to allow the recombination operator to use information regarding the problem constraints (to construct feasible descendants), and possibly the fitness values of configurations $y \in S_{\text{par}}$ (to bias the generation of descendants toward the best parents). A typical example of a blind recombination operator is the classical *Uniform crossover* [23]. In MAs, researchers tend to refer to those blind recombination algorithms as “crossover” that have low computational complexity. Currently, MAs are increasingly using recombination operators that exploit problem knowledge well [18–20,24] (commonly referred to as *heuristic* or *hybrid* recombinations). In these operators, both problem- and instance-specific information is employed to create new solutions. Examples that use problem domain information in different ways are *dynamically optimal recombination* (DOR) [25], *patching-by-forma completion* [22], and *edge assembly crossover* (EAX) [26], which has an analogy with the one proposed in Ref. 11.

A Very Simple Memetic Algorithm Template

A generic template for a MA is shown in Algorithm 1.

Algorithm 1. MA-Based Search Engine

```

begin
  Initialize pop using GenerateInitialPopulationOfAgents()
  Repeat
    newpop ← GenerateNewPopulationOfAgents(pop)
    pop ← UpdatePopulationOfAgents(pop)
    If pop has converged then
      pop ← RestartPopulationOfAgents(pop)
    Endif
  Until TerminationCriterion()
end

```

The `GenerateNewPopulationOfAgents` procedure is at the core of MAs. Essentially, this procedure can be seen as the search engine of a MA. New solutions are generated

at this step, which in general involves the exchange of pieces of information gathered in previous optimization steps. It is an increasingly more common strategy to develop MAs

in which the agents use different strategies (*blend heuristics* [7]). We also have MAs in which an *algorithmic portfolio* [27] is employed by the agents to optimize the configurations they have assigned. New individual optimization strategies can also be generated in a process that evolves not only solutions but solutions methods (i.e., coevolutionary MAs). The `UpdatePopulationOfAgents` procedure involves the optimization of current configurations being explored and the selection of a set of solutions to be further contemplated as necessary to continue the search process. The `GenerateInitialPopulationOfAgents` procedure generates an initial set of $|pop| \geq 2$ agents, each initially having at least one configuration of the search space and a set of algorithmic strategies to use. In some cases, the initial configurations are chosen at random or via more elaborate strategies (typically by application of individual optimization methods or constructive heuristics [28]).

Several criteria can be used to evaluate the loss of diversity of a population, which then triggers the request to restart the population in other regions of configuration space. There are also different types of termination criteria used, via simple computations such as attaining a certain limit on the total CPU time (or number of iterations), attainment of a maximum number of iterations without improvement, or a maximum number of population restarts. In many papers, these criteria have been generally dictated by the need for fair comparisons against population-based methods that do not employ exchange of information between agents. Consequently they are, together with smart restart procedures, fertile ground for further exploration of methodologies.

Criteria for Designing an Effective Memetic Algorithm

There is no single approach for the design of effective MAs, but there are generic rules that have worked well in practice. These *design heuristics* have collectively found good-performing strategies in several problem domains. It is, however, impossible to guarantee that the same strategy that is working well with one particular problem

will work well for all types of problems. It is in the instantiation of the previous template with precise problem-dependent components where the skills of MA design are applied (and where the use of problem domain information becomes essential).

We mentioned before that the representation of solutions in terms of “meaningful information units” is essential. Several measures have been used as a proxy for this “meaningfulness” property, such as the variability of the objective function for solutions carrying a common set of features [22,29], or the interaction (nonadditive effects on the objective function) among these information units [22,29], among others. In essence, these measures try to capture the fact that the fitness landscape has to exhibit a certain regularity that can be exploited by the search algorithm. In addition to that design requirement (recall that the fitness landscape is given by the choice of representation and operators), there should also be a good synergy between the individual optimization strategies of the MA and the type of recombination operators used. We often note the case put forward by Freisleben and Merz [30] for the TSP in which the authors first noted that a highly intensive local search procedure (Lin–Kernighan; [31]) produced local optimums that closely resemble each other, thus the global optimum (which is one of them) should be searched with a synergistic local search strategy. For this reason, they introduced a *distance-preserving* recombination operator that generates new solutions whose distance (measured in number of different edges between a pair of tours) from the parents is the same as the distance between the parents themselves. It is customary in MAs to first experiment with the individual optimization search strategies of the agents and, when some experience has been gained, design a recombination operator that works as a complement to the individual search processes.

Selection Strategies and Population Structure

The selection of optimization strategies for the agents is vital, along with adequate parameterizations of the basic procedures. It

is often the case that a simple parameterization may help in diversifying the search processes when necessary. Designers should also have other considerations such as when it is proper to stop individual optimization for a given agent, how often it should be applied, to which agents it should be applied, how to select which solutions should have “deeper” search processes, and so on [32,33]. Although these complex rules have shown to provide clear benefits, other population management strategies are also found in the literature. The use of strategies to control the loss of diversity of the population was always a concern in MAs since their foundation. Algorithmic strategies that aim to directly address this issue, via control mechanisms, are currently being proposed since the population sizes of MAs are smaller than in other evolutionary computation methods (e.g., “population management” [34–37]). Other strategies include *random selection*, *fitness-based selection* (only the best individuals are subject to local improvement), and the *stratified approach*. In this case, the population is sorted and divided into n levels, with n being the number of local search applications, and one individual per level is randomly selected [38].

There are several criteria for selecting which individuals will be subject to individual optimization. Some of them restrict this by the use of *population-structured MA* [18,39–42], where good solutions evolve within a tree-structured population. Since 1992 [7], Moscato and his collaborators have been experimenting, with a population structure-based on a ternary tree [18–20,41–46] for an effective, yet undirected and static, mechanism to control a premature loss of diversity. A comprehensive computational study in 2004, on the Asymmetric TSP, showed the benefits of introducing this strategy [39]; we expect that more research into this aspect of MAs is guaranteed. We also note that early MAs were also based on population structures [1,9,11,47,48] and this is yet a field with untapped potential as not many researchers have fully explored it.

In the case where the computation of the guiding function is costly, some researchers

have developed fast approximate models of the true guiding function to help accelerate their MAs [49–53]. Other strategies include allowing that not every configuration be subject to optimization steps (so-called *partial Lamarckism* by some authors [54–56]). While these algorithmic decisions tend to be problem dependent, with time, most researchers in MAs move toward the simplest, parameter-free techniques, or they establish *adaptive* and *self-adaptive* mechanisms to learn-on-the-fly the most appropriate parameter setting. We discuss this issue in the section titled “Adaptive Memetic Algorithms.”

ALGORITHMIC EXTENSIONS OF MEMETIC ALGORITHMS

Complete Memetic Algorithms

Complete MAs can be approached from both a sequential and an intertwined perspective. *Sequential approaches* are those in which the execution of an MA is followed by an exact method, for example, *Branch-and-Cut* (see Ref. 57 for an example). *Concurrent approaches* also exist; Denzinger and Offerman [58] combine genetic algorithms and *Branch-and-Bound* techniques within a parallel multiagent system. Cooperation of these algorithms can also be found in Refs 59 and 60, in which the exact technique provides partial promising solutions, and the metaheuristic is in charge of returning an improved bound. *Beam search* and full-fledged MAs can be found in Refs 61–63. Exact algorithms, such as *Branch-and-Bound* [25] or *Dynamic Programming* [64], among others, have provided powerful recombination algorithms (recall the section titled “Recombination and Mutation”).

This trend is perhaps not so new; using exact techniques to solve some subproblems provided by evolutionary algorithms dates back to 1995 [59,60]. Fernandes and Lourenco [65] also give a large list of references regarding local search/exact hybrids. Also, recently, Puchinger and Raidl [66] classified methods of this kind in which algorithmic combinations are *collaborative* (sequential or intertwined/concurrent execution) or *integrative* (one technique works

inside the other one, as a subordinate). Employing an exact technique to explore neighborhoods is indeed an example of an integrative approach. Further examples are the use of Branch-and-Bound in the decoding process [67] of a genetic algorithm or the use of evolutionary computation for the strategic guidance of Branch-and-Bound [68] (exemplifying the use of a metaheuristic approach within an exact method).

In spite of the fact that they use exact techniques along with metaheuristics, most of these hybrid algorithms are not complete, as they do not guarantee an optimal solution. However, they can be readily modified to achieve completeness. Exceptions exist, like French *et al.*'s [69] proposal of combining an integer-programming Branch-and-Bound approach with genetic algorithms for MAX-SAT, and the famous CONCORDE package for the TSP developed in the past decade due to the combined talents of Applegate, Bixby, Cook, and Chvatal [70], which is regarded by many as the most complex MA ever built for an optimization problem. In their approach, a local search algorithm (chained Lin–Kernighan) produces a collection of tours, followed by the DOR method called *tour merging*. This scheme has shown to produce a nonoptimal tour only 0.0002% above the proved optimal tour for 13,509 cities. Even today, one of the best local search methods for the TSP (Helsgaun's LKH code) now implements multiparent recombination, showing once again the increasing importance of this scheme (again referred to as *tour merging* in LKH-2 Version 2.0 [71]).

Multiobjective Memetic Algorithms

Multiobjective problems are frequent in real-world applications that present multiple, partially conflicting objectives. The notion of Pareto-dominance is a key: given two solutions $s, s' \in \text{sol}_P(x)$, s is said to dominate s' if it is better than s' in at least one of the objectives, and it is no worse in the remaining ones. This induces a partial order $<_P$, and the resulting collection of optimal solutions is termed the optimal *Pareto front*, or the *optimal nondominated front*. We refer readers to Refs 72–75 for more information on this topic. Multiobjective MAs adapt

local search processes in different ways [76], typically *Pareto-based* [77] and *scalarizing* approaches [78,79]. Several multiobjective MAs (MOMAs) exist like those developed by Ishibuchi and Murata [80,81] and Jaszkiewicz [82,83]. They employ random scalarization each time a local search is to be used. A single-objective local search could be used to optimize individual objectives [84]. We refer to Ref. 85 for an approach which, although originally designed for a biobjective capacitated arc routing problem (CARP), it is nevertheless, highly competitive on instances originating from single-objective CARP problems. Such studies allow researchers to have a better understanding of the power of these methods. Ad hoc mating strategies based on the particular weights chosen at each local search invocation (whereby the solutions to be recombined are picked according to these weights) are used as well. A related approach, including the on-line adjustment of scalarizing weights, is followed by Guo *et al.* [78,86,87]. On the other hand, an MA based on PAES (Pareto Archived Evolution Strategy) was defined by Knowles and Corne [88,89]. More recently, an MOMA based on a basic particle swarm optimization (PSO) has been defined by Liu *et al.* [90,91]. In this algorithm, an archive of nondominated solutions is maintained and randomly sampled to obtain reference points for particles. A different approach is used by Schuetze *et al.* [92] for numerical-optimization problems. The continuous nature of solution variables allows using their values for computing search directions. This fact is exploited in their local search procedure (HCS for Hill Climber with Sidestep) for directing the search toward specific regions (e.g., along the Pareto front) when required.

Adaptive Memetic Algorithms

In MAs, as in other novel metaheuristics converging to this paradigm, we need to customize individual search strategies for the particular problem [93]. *Parametric* adaptations exist, for instance, like modifications of operator application rates (see Refs 8 and 94); this type of adaptive strategy also exists in MAs [95–98]. The *meta-Lamarckian learning* [99] strategy works at an algorithmic

level by considering the setting in which the MA has a collection of local search operators available, and how the selection of the particular operator(s) to be applied to a specific solution can be done on the basis of past performance of the operator, or on the basis of the similarity of the solution to previous successful cases of operator application. Some analogies with *hyperheuristics* [100,101] exist.

Self-adaptation refers to the use of mechanisms that evolve the search algorithms during the run of a MA [102]. In Ref. 103, it was already envisioned that MAs should and would evolve in at least two levels and two time scales. In a short-time scale, a set of agents would be searching in the search space associated with the problem. The long-time scale would *adapt all the*

algorithms associated with the agents (i.e., recombination, individual search strategies, etc.). Examples of this methodology are the *multimemetic algorithms*, in which each solution carries a gene that indicates which local search has to be applied on it and other more complex methodologies currently under intensive development in MAs [104–108].

APPLICATIONS OF MEMETIC ALGORITHMS

We refer to applications produced before 2004 by consulting Refs 109–112. References are listed as belonging to five major areas: production planning and management science (Table 1), traditional combinatorial optimization (Table 2), electronics, engineering, and telecommunications (Table 3), machine learning and knowledge discovery (Table 4), and bioinformatics and biomedical research (Table 5). As mentioned before, we have tried to be illustrative rather than exhaustive, noting some selected references from these well-known application areas.

There are several applications of MAs in economics, for example, in portfolio optimization [294,295], risk analysis [296], optimal winner determination problem [297], time series forecasting [298], and labour-market delineation [299].

CONCLUSIONS

MAs have shown an impressive record of success in solving an ample variety of problems, owing to its pragmatic approach to optimization. The generally complex structure of MAs, blending together elements from diverse metaheuristics, makes them harder to analyze from a theoretical point of view though. Subsequently, the past decade has witnessed a remarkable increase in our theoretical understanding of MA-specific issues such as the relevance of local search depth and intensity [33,300], or the complexity of provably good multiparent recombination operators [301]. This understanding of the underlying theoretical issues will foster in upcoming years, and should lead to a more

principled approach to MA design for specific problems.

We face a future in which computing will be pervasive, and MAs can flourish in this scenario. Indeed, the sheer computational power and the distributed nature of computing resources will provide an opportunity for increasingly complex MA models envisioned in the past and only recently explored in practice, such as multilevel MAs in which evolution takes place at both the solution and the heuristic level [104–108] or large-scale cooperative models involving exact techniques. Increasingly complex solvers will be required to tackle the increasingly complex optimization problems that will appear in the future, and MAs will play a paramount role here.

METAHEURISTICS FOR STOCHASTIC PROBLEMS

LARS MAGNUS HVATTUM

Technology Management, Norwegian
University of Science and
Technology, Trondheim, Norway

The story of metaheuristics is one of success, especially when considering their application to computationally intractable optimization problems. At the same time, the understanding that many real-world problems are inherently stochastic has led to research on how this stochasticity should be modeled and handled to provide useful support for decision makers. Metaheuristics are natural candidates when stochastic problems are considered, given their history of solving difficult optimization problems. In this article, we assume that the reader is familiar with the basics of metaheuristics and has some general understanding of stochastic problems. Good introductions to metaheuristics can be found in Refs. 1–3.

Stochastic optimization problems are simply problems where some element of randomness is involved. This includes a wide variety of problems, and the numerous ways of modeling such problems reflect this variety. Among the most typical models are *stochastic programming problems* (SPPs) [4] and *Markov decision processes* (MDPs) [5], and exact solution methods for SPPs and MDPs have been studied by many researchers. For some stochastic problems, typically arising from *chance-constrained programs* (CCPs) or in robust optimization [6], deterministic equivalents exist that allow the problem to be handled as a normal deterministic problem. When using metaheuristics, one relies less on a proper mathematical formulation of the problem at hand; a formal model may be used to describe the problem, but is not a requirement. As the burden of proving optimality is relaxed,

a heuristic solution method has additional degrees of freedom when representing the reality and presenting solutions to the decision maker. The problem can then readily be documented with nonstandard models, such as eclectic models combining SPPs and MDPs [7]. Sometimes when applying metaheuristics a formalized model is omitted, especially if the model would be too intricate to interpret and too complex to solve using standard exact methods, and instead, the problem is described verbally. The field of *simulation optimization* [8] is appropriate when a simulation model can be built for a problem that is otherwise too complex to model mathematically. Multiobjective models often arise naturally in stochastic settings, either as a method to simultaneously consider solution quality, robustness, and flexibility [9], or to consider a trade-off between violating soft constraints [10].

Considering the popularity of metaheuristics and the increasing focus on stochastic problems, there is no surprise that there is already a decent amount of relevant publications to be found. It is not within the scope of this article to cover the entire field, and readers searching for further references can consider a recent survey on metaheuristics for stochastic combinatorial problems [11] and a 2005 survey [12] on evolutionary optimization in uncertain environments. We will focus on *how metaheuristics must be adapted when applied to stochastic problems*: what are the main issues that need to be considered when using metaheuristics to solve stochastic problems, as opposed to deterministic problems.

The field of metaheuristics now comprises a large number of methods and variations. Combined with the trend of making hybrid methods, it is increasingly difficult to classify metaheuristics in any meaningful way. Nevertheless, we choose to divide our discussion of how to apply metaheuristics to stochastic problems into three parts: First, we discuss local search-based metaheuristics and how these can be adapted to handle stochastic problems in the section titled

“Local Search-Based Metaheuristics”. Next, construction-based metaheuristics are examined in the second section. Then, we look at population-based metaheuristics in the subsequent section. The techniques discussed in any of these three parts should, however, be considered as potential improvements for methods that are described in the other parts; there are still ample opportunities to benefit from combining ideas of different camps of metaheuristics researchers. In the section titled “Conclusions” we present our concluding remarks.

LOCAL SEARCH-BASED METAHEURISTICS

The foundation of local search is the ability to evaluate a huge number of candidate solutions generated by applying neighborhood operators to a current solution. For deterministic problems, evaluating an arbitrary solution can usually be accomplished in polynomial time, and evaluating a neighboring solution can often be done in constant time when proper data structures are used. For stochastic problems, the outcome of one variable might be dependent on the outcome of another variable in such a way that the exact evaluation of a solution will take an exponential amount of time [13]. It is sometimes possible to do better within a local search. An example of this is Refs 14 and 15 where the evaluation of a single solution of one particular stochastic problem is reduced from an exponential number to $O(n^3)$ operations. Furthermore, it is shown how the complete neighborhood of $O(n^2)$ neighbors can also be evaluated using only $O(n^3)$ operations. However, as illustrated by Bianchi and Campbell [16], finding efficient ways to explore neighborhoods, and making sure that the resulting formulas are correct, is challenging.

When an exact evaluation of a neighboring solution is impossible, either due to the computational effort required or due to the lack of an explicit evaluation function altogether, there are two main alternatives [11]: to use an ad hoc approximation of the objective function, or to use sampling to estimate the value of the solution. For both alternatives there is a trade-off between precision

and speed, considering the computational burden of different ad hoc approximations or the number of samples used in estimation. In Ref. 17 two different proxies to replace an exact move evaluation are tested, and the most simplifying approximation seems to give the best results after a specific fixed time limit, at least for the particular problem instances considered. The use of sampling usually implies that the solution must be evaluated from scratch, but Ref. 18 gives an interesting example where sampling is used within delta evaluations. In delta evaluations, one evaluates only the changes in the solution that result from making a move, so that only a partial solution is evaluated. While efficient exact evaluation techniques often rely on the order in which neighbors are examined and require that the full neighborhood is explored [15,16], the use of sample-based delta evaluations allows efficient use of neighborhood reduction techniques.

Tabu Search

An early use of tabu search (TS) for a stochastic problem is shown in Ref. 19. Since the exact evaluation of a move is too time consuming, it is proposed to use a proxy for the objective function. It is not required that the proxy is a good approximation of the objective function, but rather that it shows a strong correlation with the change in the objective when performing a move. It was found important to compute the true value of the objective function for each of the five best neighbors determined by the proxy when selecting a move.

In Ref. 20, a very simple TS is coupled with a simulation model that is used to calculate the objective function. The only mechanisms included are tabu tenure and the standard aspiration criterion of accepting a new best solution. At each iteration, the complete neighborhood is explored and the best neighbor is selected as the new solution. Another application using simulation to evaluate moves is for determining buffer sizes in production lines [21]. Knowledge of the problem domain, realizing the importance of bottlenecks in the production line, is used to create a candidate list strategy where only a subset of the neighborhood is evaluated at each iteration. The size of the subset of

evaluated moves increases when improving moves are made and decreases otherwise, to speed up the search. When no improvements are found, different neighbors are considered by allowing bigger changes to be made to the solution through each move.

Allowing infeasible intermediate solutions during the search is sometimes beneficial in TS [22]. This was also found to be the case in Ref. 23, where a TS was designed for solving CCPs. Simulation was used to find approximate probabilities that each constraint was violated and two alternative move evaluation functions were tested: allowing infeasible solutions with a penalty gave better results than avoiding infeasible solutions altogether.

An alternative tabu criterion is suggested in Ref. 17: the cost evaluation of a non-tabu move is skipped with a low probability, whereas the cost evaluation of a tabu move is skipped with a high probability. An evaluated non-tabu move is accepted if an improvement is made, whereas an evaluated tabu move is accepted only if it leads to a new best solution. The approach is unfortunately not compared with a conventional TS implementation.

Simulated Annealing

Two techniques that can be used in simulated annealing (SA) for problems involving solutions evaluated through simulations are an acceptance criterion based on confidence intervals [24] and a constant temperature [25]. The acceptance criterion implies that the probability of accepting a nonimproving move is larger when the sample size is smaller. A constant temperature greater than zero gives the search freedom to aggressively move around the search space and locate good solutions quickly, although the Markov chain associated with the search may not converge to the set of global optimal solutions. With a combination of the two techniques, it can be shown that the most often visited solution in an SA converges almost surely to the optimal solution [26].

If the noise in the objective function evaluation can be reduced gradually during the search, for example by increasing the sample size, convergence proofs even for the current solution remain valid [27]. This

means that less effort can be used to estimate objective functions early in the search, and that the accuracy should be increased when the temperature is decreased. In Ref. 28 the error in sampling is used instead of temperature, which gives very similar behavior if the error has a normal distribution: the effective temperature corresponds to the standard deviation of the estimated change in objective function value for the move in question. Increasing the number of samples corresponds to reducing the temperature, but it was observed that a smoother annealing could be obtained by directly controlling the effective temperature.

The case of solving multiobjective stochastic combinatorial optimization problems using SA was investigated in Ref. 29. The SA follows an implementation for deterministic problems, but uses estimation based on sampling whenever an evaluation of the objective function is required. To spend more effort in crucial moments, three different sample sizes are used, depending on whether a solution is considered for inclusion in the approximation of the pareto front, for move acceptance, or for comparing with other solutions for which the local search is performed in parallel. Inclusion in the approximated pareto front is only considered when the temperature has fallen below a certain threshold.

Iterated Local Search

Iterated local search (ILS) is used in Ref. 18 for the *probabilistic traveling salesman problem* (PTSP). The ILS is based on sample-based delta evaluations, but otherwise follows a standard implementation. The sampled demand realizations used in the delta evaluation are kept throughout the search. Sampling the realizations anew after each perturbation did not yield significantly different results. For some problem instances, the variance of the cost estimates in the delta evaluations is high. Instead of just increasing the number of samples from the offset, Balaprakash *et al.* [30] examine an adaptive sample size as well as the use of importance sampling. The adaptive sampling size involves adding samples until a student's t-test shows significance or an upper limit on the number of samples is reached.

Importance sampling is a general variance reduction technique. It entails sampling from a biased distribution, making events with very low probability appear more often, and then correcting the result with likelihood ratios. The latter proves valuable for problem instances where some of the customers has only a small probability of appearing.

Variable Neighborhood Search

A variable neighborhood search (VNS) for stochastic combinatorial optimization problems is developed in Ref. 31. The focus is on problems where the objective function has a random component and is difficult or even impossible to compute. The basic VNS method is followed, but is extended by using sample average estimates as an estimator of the true objective function value for any given solution. An additional step is added to compare the current solution with the best solution found so far, again using sample average estimates but with a potentially larger sample size. A convergence proof is given, although as is typically the case for metaheuristics, a realistic implementation would not adhere to the assumptions of the proof. An important point is that the sample size used when challenging the best solution found should increase for every round of the search.

CONSTRUCTION-BASED METAHEURISTICS

While both local search-based metaheuristics and evolutionary metaheuristics have received much attention, construction-based metaheuristics have to some degree been overlooked. Constructions can conveniently allow diversification, at the expense of intensification, which may be an advantage in certain complex search spaces that can arise in stochastic problems.

Ant Colony Optimization

An ant system-based algorithm for infinite horizon discounted reward MDPs was described in Ref. 32. An ant will construct a policy by finding a walk in the following directed construction graph: each state of the Markov process is a node in the construction

graph, the out-going arcs from a node correspond to the possible actions to take when present in that state. All arcs going from one node will enter one other node, based on an arbitrary sequence of states. When the ant reaches the final node in the graph, it will have selected one out-going arc from each of the nodes corresponding to each of the states, thus representing a complete policy. An aspect of this ant system-based algorithm that is special to the application to MDPs is that of generating an elite policy for each generation of ants. This elite policy is a combination of the previous elite policy and all ants in the previously completed generation. By using the concept of policy switching [33], the elite policy is guaranteed to be the best policy found so far and to improve monotonically. This gives a basis for a probabilistic convergence proof, but the method has not yet been tested empirically. Another untested ant system-method, for MDPs with unknown models, can be found in Ref. 34.

Empirical results for ant colony optimization (ACO) on stochastic problems are mostly limited to the PTSP. One of the major issues that have been the focus of research is whether analytical computations or empirical estimation of the solution quality is more efficient [35]. Currently, the use of empirical estimation techniques has the upper hand. However, the use of ACO for this problem relies heavily on the use of local search, and progress in local search techniques [18,30] is closely related to the efficacy of estimation-based ACO.

For problems involving simulations or sampling to determine solution quality, an ant colony-method was outlined in Ref. 36. An interesting challenge is to compute the visibility values that are used by the ants in addition to the deposited pheromone when creating walks in the construction graph. As certain variables depend on random influence, it is suggested that the visibility values can be based either on taking expected values of the variables or on a sample of the random variables that changes for every round. In the tests performed, however, visibility values were not used. A round winner is determined based on evaluating all walks generated using a single random

sample. When the round winner is compared to the current best solution, a more involved test is used based on a larger set of samples. Both the round winner and the current best solution are reinforced through pheromone increments, although convergence proofs have been found only for the case when the round winner is not reinforced. Several alternatives for determining the current best solution were examined in Ref. 37, such as using a single sample, using several samples as in Ref. 36, and using a series of nonparametric statistical tests in a procedure called F-Race. This procedure is a general method for comparison of a number of candidates and selecting the best. Here, it was used to determine the best solution among all the solutions produced at the current iteration and the previous best solution. The use of F-Race seems to dominate both the use of a large iteration-dependent number of samples as well as the use of an adaptive number of samples based on parametric tests. However, when the variance of the solution value is low, it seems best to use the strategy of using only a single sample to determine the best solution.

In Ref. 29, ACO is used to solve multiobjective stochastic combinatorial optimization problems, where the objective function values are found through sample-based estimation. Round winners are determined by comparing the weighted sum of each objective function, using a single scenario. A global best solution subject to a particular random weighting of the objective functions is determined among round winners by averaging the weighted sum of objective functions over a number of scenarios. Global best solutions are then considered for inclusion in the approximation of the pareto front, based on an evaluation over a third set of scenarios.

Greedy Randomized Adaptive Search Procedure

The *stochastic inventory routing problem* (SIRP) has been formulated as an infinite horizon discounted reward MDP. A method based on Greedy Randomized Adaptive Search Procedure (GRASP) was developed for the SIRP in Ref. 38. The main idea was that the stochastics and dynamics

of this particular infinite MDP could be approximated by a finite scenario tree. A scenario tree would be created for each state encountered, and by controlling the width and height of the tree, a balance would be found between the computational effort required, the precision of the representation of the stochasticity, and the avoidance of end-of-horizon effects. Both the action space and the state space of the problem are large, so all proposed solution methods must be evaluated using simulations.

In the typical GRASP implementation one is allowed to fix any one decision at each step of the construction, which would imply that actions at every node of the tree could be modified at each step of the construction. Since the scenario tree consists of a large number of nodes, it is costly to reevaluate decisions at all nodes affected by the last decision made. An alternative that was shown effective in Ref. 38 was to perform the GRASP in a top-down fashion on the scenario tree, thus first fixing all decisions at the root node before continuing recursively down the tree. Of importance when applying this strategy is that the GRASP must include learning strategies [39], to make sure that information based on the actions selected at the bottom of the tree will eventually influence decisions at higher nodes. The usual conduct of GRASP is that once a variable has been assigned a value in the construction, that value will remain fixed for the remainder of the construction. A softer construction step was adopted where a value assigned could still be increased at later steps of the construction, which slightly reduced the consequences of each construction step, especially when the recursive top-down construction was not in force. The GRASP was also adapted to solve single scenarios and used in a progressive hedging-based decomposition method [40].

POPULATION-BASED METAHEURISTICS

Evolutionary algorithms are perhaps the most widely employed class of metaheuristics for stochastic problems. A survey [12] on evolutionary optimization in uncertain

environments pinpointed many of the critical issues to consider when using population-based metaheuristics: techniques to handle noisy or approximate evaluation (fitness) functions, to search for robust solutions, and to tackle dynamic problems. A thorough survey of approximations in fitness evaluations can be found in Ref. 41.

Genetic Algorithm

Three different techniques to overcome noisy evaluations were discussed in Ref. 42. First, the obvious choice is to take the average value over several samples. Second, it is possible to increase the population size used by the GA. This can be based on models for calculating the probability of selecting the correct building blocks, which in turn depends on both the size of the population and the different sources of noise. Obviously, increasing the population and increasing the number of samples per solution both increases the overall computational effort, but there are no definite results as to how one can best balance the two techniques. The third option discussed is called inheritance of rescaled mutations, which was examined in the context of evolution strategies (ES): big mutations are made, the best change is selected based on evaluations of the big mutations, and the best mutation determines the direction of change, although only a smaller mutation is actually recorded for the next iteration. This alternative seems to be applicable only to continuous search spaces.

An example of applying ES to a continuous problem is in manufacturing, where the decision variables are the scheduled start times of each operation, the duration of each operation is stochastic, and each candidate solution is evaluated using simulations [43]. ES was compared to SA and found to converge slower, but to better solutions. The idea that determining the difference in rank is easier than determining the difference in value was then used to improve the speed of the ES [44], by first using a small sample size to remove the worst new individuals from further consideration before doing further selection based on a large sample size.

A method called *evolutionary policy iteration*, based on genetic algorithmss (GAs), has

been proposed for infinite horizon discounted reward MDPs [33]. Instead of the usual parent selection, subsets of arbitrary size are generated from the current population and are used to generate new solutions. Each subset results in one new solution based on a mechanism called policy switching. Two levels of mutations are used: a local mutation that results in small changes to the solution and a global mutation that gives larger changes. By also creating a special elite solution from each population, which by using the policy switching mechanism is guaranteed to be at least as good as any solution from the population, the evolutionary policy iteration method can be shown to converge to the optimal solution when the number of iterations goes to infinity.

An example of a distributed GA that operates in parallel on a network of workstations is given in Ref. 45. From a modeling perspective, the stochastic labor scheduling problem that is studied differs from the deterministic version simply by the number of labor requirement constraints per time interval, with one constraint for each possible realization of labor demand. The GA in question allows some infeasible solutions in the population by adding a penalty term to the fitness evaluation, but no experiments are shown to assess the effect of this choice with respect to the increased number of constraints arising due to the representation of the stochasticity.

A stochastic one-machine scheduling problem is studied in Ref. 46. The authors distinguish between quality robustness and solution robustness, with the former being a measure of robustness for the objective function when changes occur in the problem data, and the latter being robustness with respect to the amount of changes in the solution upon reoptimization after new information is revealed. It is argued that in some cases it is desirable to find solutions that most likely will remain mostly unchanged upon reoptimization. The problem is solved by a GA using a multiobjective fitness function, consisting of a weighted sum of the solution robustness and the quality robustness. Adding a local search operator to the GA appeared to overemphasize solution quality,

and even a slightly unfavorable stochastic outcome could necessitate important modifications of the resulting job-shop schedule. Therefore, the authors argue that local search should not be performed when dealing with the stochastic variant of the problem, although it remains unclear whether a suitably modified local search would be able to efficiently overcome this issue.

When GA is used in simulation optimization, there is a question whether one can decide *a priori* whether some simulations are unnecessary. Using domain knowledge seems to be a reasonable way to discard potential solutions before evaluating them with a costly simulation. In Ref. 47 a neural network was trained during the execution of the GA and after some initialization period, was used to filter out solutions with less potential.

The number of samples used to evaluate the fitness represents a trade-off between precision and time consumption. However, an increase in the precision of the fitness evaluations is perhaps not necessary for all solutions encountered, but only for the best ones [48]. One alternative is to gradually increase the number of samples used, and to reevaluate fitness when an increase is made. Thus, generating samples during the optimization can be better than fixing a set of scenarios before performing any optimization, especially when the number of potential scenarios is large [49]. Another suggestion is to use only one sample in fitness evaluations but to recalculate the fitness using a different sample every generation. The fitness calculations are then assumed to reflect the fluctuations created by the stochasticity [50], and the solution most frequently appearing in the population is assumed to be a good one, although Yoshimoto and Yamaguchi showed that a further examination of the set of the most frequent solutions can give improved results [51].

The use of multiple types of cross-over operators was examined in Ref. 52, and the resulting diversified cross-over operator was shown to be superior to the use of any single standard cross-over operator for the *heterogeneous PTSP*.

Scatter Search

Compared to GAs, the evolutionary meta-heuristic scatter search (SS) has received little attention. However, even when standard implementations are used as a black-box, the method can be successful: in the study by Yang *et al.* [53] it seemed better than a response surface method when considering two responses simultaneously. Using a standard implementation, Ref. 54 focused on variance reduction techniques, such as common random numbers and antithetic variates, and on dynamically adjusting the number of simulations performed to reduce the computational effort required to reach certain confidence interval widths for solution evaluations.

As an improvement method can often be time consuming for stochastic problems, Liu [55] suggested that the improvement method should be dropped unless the solution to be improved has a sufficiently high quality relative to the best solution in the reference set. Using approximate evaluations can help decrease the computational burden, and even when an improvement method based on local search is time consuming, it can be worthwhile to combine several different neighborhood operators [56].

Several alternatives to the standard SS implementation are proposed in Ref. 57. They consider problems where the objective function is given by a simulation process, although noisy evaluations are not considered, and where some constraints are given as differential equations describing system dynamics. Infeasible solutions are allowed but penalized based on the maximum percentage of violation. In a standard SS, building the initial reference set requires that all solutions in the original pool are evaluated using costly simulations. The suggested alternative is to build the initial reference set by only adding solutions that maximize diversity, after initially including three solutions where all variables are either at their lower bounds, their upper bounds, or at the midpoints of their bounds. This alternative saves computational effort at the expense of a reference set containing fewer high quality solutions. An interesting extension is made to the reference set update

mechanism: the standard update can lead to reference sets with very similar solutions. This could be particularly true for problems with a flat solution landscape, where one has many solutions with relatively similar objective function values which can often be the case for stochastic problems. The extension relies on a distance filter and an aspiration criterion: solutions are only added to the reference set if they can replace a worse solution and if they are sufficiently different from the rest of the reference set. They are, however, always added if they represent a new best solution found. Another change is that the reference set is not only rebuilt when no combined solution qualifies to enter, but also if the reference set becomes too homogeneous, either in terms of distances or objective function values.

Particle Swarm Optimization

Most work using particle swarm optimization (PSO) for stochastic problems seems to apply more or less standard implementations, for example Ref. 58, although the calculation of the fitness of particles may not be readily available in closed form [59]. An interesting example is given in Ref. 60, where an adaptive PSO is used both for generating a multistage scenario tree and then for solving the optimization problem based on the scenario tree. Although the use of PSO to generate scenario trees is not compared to other scenario tree generation methods, it does illustrate how metaheuristics can be used also when determining how the stochasticity can be represented, and not just to solve the problem once the stochasticity has been defined.

The ability of standard PSO heuristics to cope with noise was examined in Ref. 61. In PSO, noise affects every iteration when the solution of a particle is compared to the previous best solution of the particle, as well as when the overall best solution is determined. The authors conclude that noise can lead to stagnation, where better solutions are not accepted as such due to random noise, or to a search that is misguided by solutions that appear to be better than they are. Furthermore, the resulting stagnation can not be removed by parameter optimization alone,

but requires reduction of noise, for example through averaging over multiple samples.

CONCLUSIONS

In this article we have tried to illustrate a selection of issues that arise when using metaheuristics to solve stochastic optimization problems. Some metaheuristics have received attention in numerous publications, for example GAs, which have mostly been applied to problems with continuous variables [12,41]. Other metaheuristics have been tested on stochastic problems in only a few cases, or never at all.

A major concern when implementing metaheuristics for stochastic problems is that of efficiently evaluating solutions. This is sometimes accomplished through problem-specific analysis to provide quick, exact evaluations, sometimes by providing ad hoc approximations or proxies to generate evaluations, and sometimes by using filters to avoid evaluating unpromising solutions. Often the evaluation of solutions is handled by averaging over a set of samples. The sampling method is facilitated by recent developments in electronics: processor manufacturers pack more computing cores in each chip instead of reducing the sizes of the transistors as a primary means of increasing processing power. Parallelization of metaheuristics for stochastic problems therefore seems promising, in particular, when the evaluation of a given solution requires multiple simulations that can be performed on separate processor cores.

One lesson from research on heuristic search methods is that domain-specific knowledge is important [62], and that methods that easily allow the incorporation of such knowledge can have an advantage. There are two ways to include knowledge in a search: it can be specified *a priori* in the design of the search, for example where neighborhood structures are composed so that good moves will lead to promising parts of the search space. Alternatively, it can be formed *a posteriori* based on the search history, with metaheuristic components that analyze and learn from the attributes of

visited solutions. Most of the adaptations of metaheuristics for stochastic problems have focused on components that represent the former type of knowledge: finding efficient methods to evaluate solutions, showing how the use of multiple neighborhoods or cross-over operators can facilitate a better search, or tuning parameters such as population size in GAs to better handle problems with noise. Efficient inclusion of *a priori* knowledge is an important step toward successful metaheuristics for stochastic problems, but learning from search history may also prove beneficial: ACO achieves this to some extent through pheromone updates, and the GRASP in Ref. 38 includes learning as a central mechanism. Other examples include adaptively changing the number of samples used to evaluate solutions based on statistical tests, and the use of artificial intelligence techniques to estimate objective function values. Learning mechanisms that use search history to provide a balance between intensification and diversification [1,63] could be important: knowledge about the structure of stochastic problems, with solution quality depending on the interaction of many stochastic parameters, may be difficult to incorporate *a priori* in the search, but components using learning could potentially be used to find and exploit such structures.

A topic that deserves more attention is the coupling of exact and heuristic methods. For example, in Ref. 64 a GA was used as a component of an exact algorithm to solve finite-horizon partially observed MDPs. On the other hand, in Ref. 7, a GA used an exact algorithm as a subsolver, with dynamic programming being used to find the optimal policy for several MDPs to evaluate the solutions generated by the GA.

Compared to exact methods, metaheuristics have the advantage of being able to handle bigger problem instances and offer a significant reduction in computation times [11]. However, there are still open questions as to how one can best apply metaheuristics to stochastic problems. As for deterministic problems, the choice of solution method is dependent on characteristics of the problem,

but it is difficult to determine which method is most appropriate for any given problem.

Acknowledgments

The authors thank the anonymous referees for suggesting several improvements to the manuscript. This work was supported by the projects *DESIMAL* and *Coping with Risk in Maritime Logistics*, both partially funded by the Research Council of Norway.

METHODS FOR LARGE-SCALE UNCONSTRAINED OPTIMIZATION

GIOVANNI FASANO
Dipartimento di Matematica
Applicata, Università Ca' Foscari,
Venezia, Italy

The general large-scale unconstrained optimization problem can be formulated as follows:

$$\min_{x \in \mathbb{R}^n} f(x), \quad (1)$$

where $f: \mathbb{R}^n \rightarrow \mathbb{R}$ is a real-valued objective function, and the parameter n is *large*. Observe that in general the minimization in problem (1) refers to the search for a *local minimizer* of $f(x)$. Standard assumptions ensure that the problem (1) admits solution. In particular, if the level set $\mathcal{L}_0 = \{x \in \mathbb{R}^n : f(x) \leq f(x_0)\}$ is compact and $f(x)$ is continuous on $\mathcal{L}_0$, then by the Weierstrass theorem (1) has a solution. Moreover, if the objective function is coercive, that is, $\lim_{\|x\| \rightarrow +\infty} f(x) = +\infty$ (which usually holds in real applications), then all the level sets of $f(x)$ are compact.

The definition of “large n ” is a little vague for the problem (1), in that it does not specify exactly a range of values and is straightforwardly machine dependent. Indeed, broadly speaking, n may be considered large on a particular machine, if standard optimization techniques for problem (1) become progressively inadequate when n increases, so that *ad hoc* methods must be adopted. Anyway, 10^6 – 10^7 may be considered a reference value for n , on a serial machine, in order to consider problem (1) a large-scale continuous optimization problem. Real-life applications increasingly yield complex models that require efficient techniques (see the Nonlinear Optimization Models collected by Robert Vanderbei on <http://www.orfe.princeton.edu/~rvdb/amp1/nlmodels>). This has led in the last

decades to a growing interest for large-scale optimization, so that the latter topic can be considered by this time a mature field of research.

Optimization methods for small- and medium-scale problems [1–4] are usually hardly adaptable to large-scale problems. Indeed, though they may be still effective in most of the cases, on problems where n is large they often prove not to be efficient enough (i.e., they are unable to solve the problems using a reasonable workload).

As for most of the algorithms for continuous unconstrained optimization, methods for large values of n claim for suitable search directions and stepsizes along them, too. In particular, the choice of the search directions is responsible for the *efficiency* of the methods (i.e., the rate of convergence), while a proper choice of the steplength ensures the *effectiveness*. When n is large, iterative methods typically show a reduced computational burden with respect to direct methods. They generate a sequence of iterates $\{x_k\}$ approaching a solution, which usually follows one of the patterns:

1. $x_{k+1} = x_k + \alpha_k d_k$ in case convergence to a stationary point x^* is sought, which satisfies the first-order necessary optimality conditions;
2. $x_{k+1} = x_k + \phi_d(\alpha_k) d_k + \phi_u(\alpha_k) u_k$ in case convergence to a stationary point x^* is sought, which satisfies the second-order necessary optimality conditions;

where $d_k \in \mathbb{R}^n$ is a search direction that approximates a Newton-type direction at x_k , $u_k \in \mathbb{R}^n$ is a search direction that takes into account the local curvature of the objective function at x_k , $\phi_d(\cdot)$ and $\phi_u(\cdot)$ are polynomial functions of degree at most two, and α_k is a suitable stepsize. The schemes in the classes 1. and 2. may typically be differentiated on the basis of the information on $f(x)$, which is available at the iterate x_k . In particular, if at x_k we can simply use $f(x_k)$, $\nabla f(x_k)$, and a

partial information on $\nabla^2 f(x_k)$, then we will be able to generate $\{x_k\}$ according to 1.

On the other hand, if in addition we get information on the eigenpair associated with the smallest eigenvalue of the Hessian matrix $\nabla^2 f(x_k)$, we can generate the sequence $\{x_k\}$ according to 2. Observe that the last statement does not imply that a full knowledge (and possibly the storage) of $\nabla^2 f(x_k)$ is required (which is commonly considered cumbersome). When n increases, though in principle the entries of the Hessian matrix could be computed by finite differences, iterative methods commonly need to perform only the product *Hessian* $\times$ *vector*, which is computationally cheaper. Alternatively, in case $f(x)$ is explicitly defined and is not a *black box*, automatic differentiation [5] is often adopted to provide information on $\nabla^2 f(x_k)$.

GLOBAL CONVERGENCE AND GRADIENT METHODS

A very general convergence result may be proved for the iterative scheme 1. Indeed, introducing the *forcing function* $\sigma : \mathbb{R}^+ \rightarrow \mathbb{R}^+$, such that $\lim_{k \rightarrow \infty} \sigma(w_k) = 0$ implies $\lim_{k \rightarrow \infty} w_k = 0$, we have [6]:

Proposition 1. *Let $\{x_k\}$ be the sequence generated by the scheme 1. starting from $x_0 \in \mathbb{R}^n$. Suppose the level set $\mathcal{L}_0$ is compact and for any k we have $d_k \neq 0$ if $\nabla f(x_k) \neq 0$, with $f(x_{k+1}) \leq f(x_k)$. Assume that*

1. *we have*

$$\lim_{k \rightarrow \infty} \frac{\nabla f(x_k)^T d_k}{\|d_k\|} = 0,$$

2. *for any k for which $d_k \neq 0$*

$$\frac{|\nabla f(x_k)^T d_k|}{\|d_k\|} \geq \sigma(\|\nabla f(x_k)\|).$$

Then, either there exists a finite index $\hat{k}$ such that $\nabla f(x_{\hat{k}}) = 0$, or the infinite sequence $\{x_k\}$ satisfies

- $x_k \in \mathcal{L}_0$ for any k ;

- the sequence $\{f(x_k)\}$ converges;
- for any infinite subsequence $\mathcal{K}$ of indices

$$\lim_{k \rightarrow \infty, k \in \mathcal{K}} \|\nabla f(x_k)\| = 0.$$

A very simple class of iterative methods for large-scale unconstrained optimization, which satisfy the hypotheses of Proposition 1, is given by the so-called *gradient methods* [4,7], which may be specified in the form

$$x_{k+1} = x_k - \alpha_k D_k \nabla f(x_k), \quad (2)$$

with $D_k \in \mathbb{R}^{n \times n}$ positive definite for any k . Observe that whenever $\nabla f(x_k) \neq 0$ the search direction $d_k = -D_k \nabla f(x_k)$ in iteration (2) is of descent at the nonstationary point x_k , and satisfies statement 2. of Proposition 1. Moreover, an Armijo-type linesearch procedure [8] should be adopted to compute α_k in iteration (2) in order to satisfy also statement 1. of Proposition 1. Of course, when $D_k = I$, for any k , then the iteration (2) reduces to the standard *steepest descent method*, which is equivalent to minimize the first-order local model of the objective function. The steepest descent method yields a linear convergence rate, and it is not scale invariant under a coordinate transformation. In case the evaluation of $f(x)$ is expensive (e.g., for several simulation problems [9]), a constant value for the stepsize α_k may be adopted in place of the linesearch procedure. On the other hand, a computationally efficient choice for α_k and D_k was suggested in Barzilai and Borwein [10] and Raydan [11], where $D_k = I$, for any k , and

$$\alpha_k = \frac{\|x_k - x_{k-1}\|^2}{(x_k - x_{k-1})^T [\nabla f(x_k) - \nabla f(x_{k-1})]}.$$

Finally, when $D_k = [\nabla^2 f(x_k)]^{-1}$ and $\alpha_k = 1$ the iteration (2) reduces to *Newton's method*, which corresponds to minimize the quadratic local model of $f(x)$ at x_k . The latter technique is appealing thanks to its quadratic rate of convergence and the scale invariance. However, when $\nabla^2 f(x_k)$ is dense and n is large, it may not be a suitable choice. In the latter case, fully computing $[\nabla^2 f(x_k)]^{-1}$ by means of a Cholesky factorization or a symmetric indefinite factorization requires nearly $1/3n^3$

floating-point operations, while for sparse Hessians the workload is proportional to the sparsity pattern.

INEXACT AND TRUNCATED NEWTON METHODS

The application of Newton's method requires one to compute the direction $d_k = -[\nabla^2 f(x_k)]^{-1} \nabla f(x_k)$, which is equivalent to solving *Newton's equation*

$$\nabla^2 f(x_k) d = -\nabla f(x_k). \quad (3)$$

When the iterate x_k is still "far" from the stationary point x^* , an accurate solution of Equation (3) may be unjustified; thus, when n is large the solution of Equation (3) may be obtained by an iterative procedure. In addition, in order to preserve the global convergence of Newton's method, a suitable choice of α_k must be computed (a globalization technique), either based on a *linesearch approach* [1,12,13] or a *trust-region approach* [14,15]. On these guidelines, for large values of n , *inexact Newton method* have been proposed

Linesearch-based Truncated Newton scheme

```

Set  $x_0 \in \mathbb{R}^n$ 
Set  $\eta_k \in [0, 1)$  for any  $k$ , with  $\{\eta_k\} \rightarrow 0$ 
OUTER ITERATIONS
for  $k = 0, 1, \dots$ 
    Compute  $\nabla f(x_k)$ ; if  $\|\nabla f(x_k)\|$  is small then STOP
    INNER ITERATIONS
    Compute  $d_k$  which approximately solves Equation (3)
    and satisfies the truncation rule
         $\|\nabla^2 f(x_k) d_k + \nabla f(x_k)\| \leq \eta_k \|\nabla f(x_k)\|$ 
    Compute the steplength  $\alpha_k$  by an Armijo-type linesearch scheme
    Update  $x_{k+1} = x_k + \alpha_k d_k$ 
endfor
```

Observe that at the outer iteration k a second-order expansion of the function $f(x)$ is considered, whose stationary point (if any) is detected by solving Equation (3). The number of inner iterations, which are necessary to approximately solve Newton's equation (3), depends on the current parameter η_k . Thus, a fine (and more expensive) solution of Equation (3) is required only when $k \rightarrow \infty$. The truncation rule (4) is often replaced in practice by more efficient conditions [22,23].

in the literature [16]. The underpinning idea of these schemes is that we can balance the computational burden of solving Equation (3) and the accuracy of the solution obtained. In particular, from Dembo *et al.* [16], if the approximate solution d_k of Equation (3) is computed, such that (truncation rule)

$$\lim_{k \rightarrow \infty} \frac{\|\nabla^2 f(x_k) d_k + \nabla f(x_k)\|}{\|\nabla f(x_k)\|} = 0 \quad (4)$$

holds, then the sequence of iterates $\{x_k\}$ is *superlinearly convergent* to a stationary point x^* . Broadly speaking, the condition (4) states that when k increases, the gradient of the quadratic local model of $f(x)$ at x_k approaches zero "more quickly" than the gradient $\nabla f(x_k)$ of the objective function. When n is large, iterative methods such as the *conjugate gradient* (CG) may be used to compute an approximate solution d_k of Equation (3), such that Equation (4) holds. The latter philosophy is based on *truncated Newton methods* [17–19], which proved to be a very efficient tool [20,21]. An example of truncated Newton method, based on a linesearch approach to ensure the global convergence, is the following:

The Hessian matrix in Equation (3) may be possibly indefinite. Thus, additional safeguard is required for the choice of the iterative solver, since for instance a negative curvature direction for function $f(x)$ at x_k may be detected, or a pivot breakdown may occur with the CG method. The Lanczos process and suitable extensions of the CG method (namely, the planar CG) may successfully be used as alternatives to the CG [24–28]. Furthermore, finite differences

have also been used in the past, in order to approximately compute the information on the Hessian matrix, within a truncated Newton method (see TNPack in Schlick and Fogelson [29]).

Three other relevant issues have been studied in the last two decades, in order to drastically improve the performance of truncated Newton methods: the *preconditioning strategies* to solve Newton's equation, the exploitation of *negative curvature directions* of the objective function, and the introduction of *nonmonotone globalization* schemes. The first issue studies efficient preconditioners of the matrix $\nabla^2 f(x_k)$, for the specific case of large n , when the Hessian is either positive definite or indefinite [14, 30–32]. The second issue needs a specific treatment when n is large, since it deals with the careful choice for the iterative solver of Newton's equation. Moreover, an accurate exploration of the negative curvatures of $f(x)$ is essential in order to prove the convergence of truncated methods toward solutions that satisfy the second-order optimality conditions [33, 34]. The latter task is pursued by computing the pair of promising search directions (d_k, u_k) at the outer iteration k [20, 25, 35–37], by means of efficient iterative techniques. Roughly speaking, d_k contains information on the local convexity of $f(x)$ at x_k , while u_k conveys information on the local nonconvexity of $f(x)$, and approximates the eigenvector corresponding to the minimum negative eigenvalue of $\nabla^2 f(x_k)$. Then, in order to guarantee the convergence to second-order points, the two directions may be combined to produce the next iterate, as in (see pattern 2 mentioned in the introductory text.)

$$x_{k+1} = x_k + \phi_d(\alpha_k)d_k + \phi_u(\alpha_k)u_k,$$

where α_k is chosen by a proper linesearch procedure. The introduction of nonmonotone globalization schemes, in truncated Newton methods, was first proposed in Grippo *et al.* [38] (see also Grippo *et al.* [13], Lucidi *et al.* [25] and Ferris *et al.* [35]). Considering the standard Armijo linesearch scheme $f(x_k + \alpha d_k) \leq f(x_k) + \gamma \alpha \nabla f(x_k)^T d_k$, where $\gamma \in (0, 1/2)$, the main idea behind a nonmonotone approach generalizes the mono-

tone decreasing of $f(x_k)$, as in the scheme

$$f(x_k + \alpha d_k) \leq \max_{0 \leq i \leq M} \{f(x_{k-i})\} + \gamma \alpha \nabla f(x_k)^T d_k,$$

where the integer M indicates the “memory” of the scheme. The nonmonotone approach proves to be particularly efficient in the case of highly nonlinear functions, where enforcing the monotonic decrease of $f(x)$ may cause the algorithms to be trapped within narrow valleys.

Global convergence of truncated Newton methods may be proved either using a linesearch framework, or adopting a *trust-region* approach [14]. A trust-region scheme provides the new iterate $x_{k+1} = x_k + d_k$ at step k (i.e., now d_k includes both the search direction and the steplength), by solving the constrained subproblem

$$\begin{aligned} \min_d \quad & Q_k(d) \\ \text{s.t.} \quad & \|\Lambda_k d\| \leq \Delta_k, \end{aligned} \quad (5)$$

where $Q_k(d) = f(x_k) + \nabla f(x_k)^T d + \frac{1}{2} d^T \nabla^2 f(x_k) d$ and Λ_k is a scaling matrix (possibly $\Lambda_k = I$, for any k), which may be regarded as introducing an implicit preconditioning. The basic trust-region approach adaptively assesses the trust-region radius Δ_k in problem (5) with the following idea: as long as the solution d_k of problem (5) yields a value for ρ_k close to 1, where

$$\rho_k = \frac{f(x_k) - f(x_k + d_k)}{Q_k(0) - Q_k(d_k)}, \quad (6)$$

$Q_k(d)$ is a “trusted” local model of $f(x)$ and the radius Δ_{k+1} may be possibly larger than Δ_k . On the contrary, if ρ_k in relation (6) is relatively small, then the model $Q_k(d)$ is not reliable and the radius Δ_{k+1} at the next iteration satisfies $\Delta_{k+1} < \Delta_k$.

When n is large, the trust-region approach requires both a strategy to assess the parameter Δ_k and an efficient procedure to approximately solve problem (5). Among the first techniques to solve problem (5), the *dogleg* schemes proposed to investigate the solution over a suitable one-dimensional arc [39, 40].

In Byrd *et al.* [41], a pair of feasible directions for problem (5) is preliminarily

computed, then the minimization of $Q_k(d)$ is performed over the two-dimensional manifold associated with the latter vectors. Another approach to solve problem (5) imposes the KKT conditions of problem (5), and solves a resulting perturbation of the Newton equation for $f(x)$ [42,43].

Since the previous approaches may recur to direct solvers (e.g., Cholesky factorization), when n is large, a different strategy is suggested in Steihaug [44] and Toint [45]. Here, CG is used to minimize $f(x)$; then, a piecewise path connecting the feasible iterates generated by CG is considered, and can be followed up to the boundary of the trust region. Alternatively, both the steepest descent direction (moving to the Cauchy point¹ on the boundary of the trust region) and possibly a negative curvature direction (in case $\nabla^2 f(x_k)$ is indefinite) are investigated. An example of a robust and reliable truncated Newton method, in a trust region rather than a linesearch framework, is given by the package LANCELOT [21]. Trust-region methods have several advantages, including the fact that they show strong convergence properties [14]. However, in case for several values of k the Hessian matrix $\nabla^2 f(x_k)$ is indefinite, these methods may be inefficient, inasmuch as they can stop the inner iterations prematurely, when approximately minimizing $Q_k(d)$. These drawbacks have been addressed and partially overcome in Gould *et al.* [26], by using the Lanczos process for the solution of large symmetric and indefinite linear systems, and exploiting its relation with the CG (see also Stoer [46]).

NONLINEAR CONJUGATE GRADIENT METHODS

The CG used for the minimization of a strictly convex quadratic function has been extended to the minimization of nonlinear functions, by suitably modifying the computation of its

coefficients [47–49]. In particular, suppose that at step k the directions $\{p_1, \dots, p_k\}$ were generated by the Nonlinear Conjugate Gradient (NCG). Then, the steplength α_k is chosen to satisfy the standard first Wolfe linesearch condition (minimization along the direction p_k)

$$f(x_k + \alpha_k p_k) \leq f(x_k) + \gamma \alpha_k \nabla f(x_k)^T p_k, \quad \gamma \in (0, 1/2) \quad (7)$$

and either one of the following additional relations (Wolfe conditions)

$$\nabla f(x_k + \alpha_k p_k)^T p_k \geq \theta \nabla f(x_k)^T p_k, \quad \theta \in (\gamma, 1) \quad (8)$$

$$|\nabla f(x_k + \alpha_k p_k)^T p_k| \leq \theta |\nabla f(x_k)^T p_k|, \quad \theta \in (\gamma, 1) \quad (9)$$

(theoretical reasons may impose the more restrictive condition $\theta \in (\gamma, 1/2)$). Furthermore, in the NCG, it is possible to adopt different formulae for the computation of the coefficient β_k used in the iteration $p_k = -\nabla f(x_k) + \beta_k p_{k-1}$. Very standard formulae for β_k in the literature are [48]

Fletcher–Reeves:

$$\frac{\|\nabla f(x_k)\|^2}{\|\nabla f(x_{k-1})\|^2},$$

Polak–Ribiere:

$$\frac{[\nabla f(x_k) - \nabla f(x_{k-1})]^T \nabla f(x_k)}{\|\nabla f(x_{k-1})\|^2},$$

Hestenes–Stiefel:

$$\frac{[\nabla f(x_k) - \nabla f(x_{k-1})]^T \nabla f(x_k)}{[\nabla f(x_k) - \nabla f(x_{k-1})]^T p_{k-1}}. \quad (10)$$

We report below a general scheme for the NCG. We remark that, apart from relations (10), several other choices for the coefficient β_k have been studied in the literature [48].

¹The Cauchy point is the minimizer of $Q_k(d)$ along the direction $-\nabla f(x_k)$, subject to the trust-region bound.

Nonlinear Conjugate Gradient (NCG) method

Step 0: Choose $x_0 \in \mathbb{R}^n$, set $k = 0$

Step 1: Compute $\nabla f(x_k)$. If $\nabla f(x_k) = 0$ then STOP

Step 2: If $k \neq 0$ compute β_k as in relations (10). Compute the direction

$$p_k = \begin{cases} -\nabla f(x_k) & k = 0 \\ -\nabla f(x_k) + \beta_k p_{k-1} & k \geq 1 \end{cases}$$

Step 3: Choose α_k such that relation (7) is satisfied, along with either relation (8) or (9)

Step 4: Set $x_{k+1} = x_k + \alpha_k p_k$, $k = k + 1$ and go to **Step 1**

Unlike the CG, the NCG does not generally retain global convergence properties, because of the loss of conjugacy caused by the nonlinearity of $f(x)$. In order to enforce global convergence, a periodic restart may be imposed, either when $k > n$ or if a test on the conjugacy loss, like

$$|\nabla f(x_k)^T \nabla f(x_{k-1})| > \sigma \|\nabla f(x_{k-1})\|^2, \\ \sigma \in (0, 1)$$

is satisfied. However, when n is large, the latter choice is impracticable (very rarely adopted) and proved to be inefficient. Using the formula of β_k , proposed by Fletcher–Reeves, in case α_k is computed by an exact linesearch procedure [50], or by an Armijo-type linesearch based on the strong Wolfe condition (9) with $\theta < 1/2$ [2,51], the global converge is retained and $\liminf_{k \rightarrow \infty} \|\nabla f(x_k)\| = 0$. In Gilbert and Nocedal [49], the global convergence was also proved for the case $|\beta_k| \leq \beta_k^{FR}$, where β_k^{FR} refers to the formula in relations (10) proposed by Fletcher and Reeves.

Though the choice of β_k^{PR} made by Polak–Ribiere (see relations (10)) proved to be computationally more efficient than β_k^{FR} [2,48], convergence properties for the NCG with β_k^{PR} have always been more difficult to investigate. In particular, the global convergence was proved under strong convexity assumption of $f(x)$, using $\beta_k = \max\{0, \beta_k^{PR}\}$, with an inexact linesearch procedure which also satisfies condition (9). Only recently [52],

by using a more sophisticated linesearch procedure, the global convergence of NCG using β_k^{PR} was proved (in the sense that $\lim_{k \rightarrow \infty} \|\nabla f(x_k)\| = 0$), without the strong convexity assumption on $f(x)$. An extension of the NCG, which uses the Polak–Ribiere value β_k^{PR} , is implemented in the routine VA14, of the Harwell Subroutine Library [53].

QUASI-NEWTON METHODS AND PARTIALLY SEPARABLE FUNCTIONS

Quasi-Newton methods are a powerful tool for large-scale optimization. They are used to solve Newton's equation, without using the second-order derivatives. In particular, these methods generate the sequence $\{x_k\}$ by iteratively solving the modified Newton's equation

$$B_k d = -\nabla f(x_k),$$

with B_k positive definite

and computing $x_{k+1} = x_k - \alpha_k B_k^{-1} \nabla f(x_k)$, where B_k in some sense *approximates* the Hessian matrix $\nabla^2 f(x_k)$ of $f(x)$. More specifically, B_{k+1} is the solution of the subproblem

$$\begin{aligned} \min_B \quad & \|B - B_k\|_F \\ \text{s.t.} \quad & B = B^T \\ & B s_k = y_k, \end{aligned}$$

where $\|\cdot\|_F$ indicates the Frobenius norm, $s_k = x_{k+1} - x_k$ and $y_k = \nabla f(x_{k+1}) - \nabla f(x_k)$,

so that no second-order derivatives are required. Several quasi-Newton schemes have been developed, using approximations of either $\nabla^2 f(x_k)$ or $[\nabla^2 f(x_k)]^{-1}$ [2,12,48,54,55]. One of the most effective, in small-scale and medium-scale optimization, is BFGS (*Broyden–Fletcher–Goldfarb–Shanno*). Here, a sequence $\{H_k\}$ of approximations of $[\nabla^2 f(x_k)]^{-1}$ is generated, with H_k being positive definite, by solving the subproblem

$$\begin{aligned} \min_H \quad & \|H - H_k\|_F \\ \text{s.t.} \quad & H = H^T \\ & s_k = Hy_k, \end{aligned}$$

so that $x_{k+1} = x_k - \alpha_k H_k \nabla f(x_k)$. Moreover, the global convergence properties can be proved by computing the steplength α_k via an Armijo-type linesearch procedure, satisfying also condition (9). It can be easily proved [2] that the matrices $\{H_k\}$ satisfy the relation

$$H_{k+1} = V_k^T H_k V_k + \rho_k s_k s_k^T,$$

where $V_k = I - \rho_k y_k s_k^T$ and $\rho_k = 1/y_k^T s_k$, so that the pairs $\{(s_k, y_k)\}$ are necessary and sufficient to generate the whole sequence $\{H_k\}$. We remark that an interesting relationship between NCG and BFGS can be stated (see Nocedal and Wright [2] or Pytlak [48]), both for quadratic and general nonlinear functions.

In a large-scale setting, the storage of V_k cannot be proposed; Thus, the formula to update H_{k+1} is suitably modified by using just the most m recent pairs (s_i, y_i) , $i = 1, \dots, m$. On this guideline, the matrix H_k is computed as

$$\begin{aligned} H_k = & (V_{k-1}^T \dots V_{k-m}^T) H_k^0 (V_{k-m} \dots V_{k-1}) \\ & + \rho_{k-m} (V_{k-1}^T \dots V_{k-m+1}^T) \\ & \quad s_{k-m} s_{k-m}^T (V_{k-m+1} \dots V_{k-1}) \\ & + \rho_{k-m+1} (V_{k-1}^T \dots V_{k-m+2}^T) \\ & \quad s_{k-m+1} s_{k-m+1}^T (V_{k-m+2} \dots V_{k-1}) \\ & + \dots \\ & + \rho_{k-1} s_{k-1} s_{k-1}^T, \end{aligned}$$

and a practical choice of H_k^0 is often $H_k^0 = \gamma_k I$, with $\gamma_k = s_{k-1}^T y_{k-1} / y_{k-1}^T y_{k-1}$. The storage of

H_k now requires only the pairs (s_i, y_i) , $i \leq m$, so that it can be defined by setting the parameter m . The resulting new sequence $\{H_k\}$ yields a very efficient method called *L-BFGS* [56–58] (where “L” stands for *limited memory*).

Observe that in practice very small values of m are used (say $3 \leq m \leq 8$) and the L-BFGS method often may be competitive with truncated Newton methods or the NCG [59]. In addition, thanks to the simplified structure of H_k , iterative Krylov-based methods may be easily applied when performing the product $H_k \nabla f(x_k)$ in the iteration $x_{k+1} = x_k - \alpha_k H_k \nabla f(x_k)$. In order to cope with problems of illconditioning of the Hessian matrix, a combined approach between L-BFGS and the discrete Newton method was studied in Byrd *et al.* [60]. The L-BFGS method was coded and is available in the routine `VA15`, of the Harwell Subroutine Library [53]. The memory storage of the NCG implemented in the routine `VA14` is $6n$, while the memory storage of the L-BFGS method implemented in the routine `VA15` is $2nm + 4n$.

When the scale n of problem (1) is large, also another strategy may be adopted to tackle a minimum point: namely, *partially separable functions* can be exploited. Suppose $f(x)$ is a partially separable function, that is, it can be written in the form

$$f(x) = \sum_{i=1}^p f_i(x), \quad (11)$$

where each of the functions $f_1(x), \dots, f_p(x)$ depends just on a subset of the unknowns x . Evidently, by Equation (11) the gradient and the Hessian matrix of $f(x)$ are given by

$$\nabla f(x) = \sum_{i=1}^p \nabla f_i(x); \quad \nabla^2 f(x) = \sum_{i=1}^p \nabla^2 f_i(x).$$

Thus, drawing our inspiration from the quasi-Newton methods, let B be a quasi-Newton approximation of $\nabla^2 f(x)$, while B_i , $i = 1, \dots, p$, is a quasi-Newton approximation of $\nabla^2 f_i(x)$. Then, numerical experiences proved that $\sum_{i=1}^p B_i$ is often a better approximation of $\nabla^2 f(x)$ than B , as long as a satisfactory quasi-Newton approximation of each $\nabla^2 f_i(x)$ is given.

The AMPL modeling language [61] contains a specific tool, which is able to compute the approximation B_i of $\nabla^2 f_i(x)$ by automatic differentiation [5], so that a sparse representation of $\nabla^2 f(x)$ is available. For other references on this topic see also Griewank and Toint [62,63], Malmedy and Toint [64] and the references therein.

MULTIGRID OPTIMIZATION

Optimization-based multigrid methods are a class of algorithms which have had a fast development in the last decade [65–67], since efficient methods for the optimization of large-scale nonlinear systems governed by differential equations are sought. In particular, let us consider the problem

$$\begin{aligned} \min_x \quad & f[x, u(x)] \\ \text{s.t.} \quad & S[x, u(x)] = 0, \end{aligned} \quad (12)$$

where $f : \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}$, and the variables $u = u(x)$, with $u : \mathbb{R}^n \rightarrow \mathbb{R}^m$, are commonly called *state unknowns* and are implicitly defined by the system of partial differential equations (PDE) $S[x, u(x)] = 0$ (*state equations*).

Optimization-based multigrid methods for solving problem (12) consider a family of optimization problems, associated with problem (12), each corresponding to a different discretization of the system $S[x, u(x)] = 0$. Intuitively speaking, the workload to solve problem (12) by choosing a finer discretization (*grid*) is larger than that by choosing a coarser grid. These methods use the computation on a coarser grid (which implies the solution of unconstrained optimization subproblems), in order to improve an approximate solution of problem (12) on a finer grid.

A very general algorithm for the latter purpose is MG/Opt, which is described in Nash [66]. This algorithm does not apply to a specific family of grids; moreover, it relies on the use of optimization models along with a linesearch procedure, in order to guarantee the global convergence of the method. Further details and a numerical experience for multigrid methods are given in Lewis and Nash [67] and the references therein.

Similar ideas for unconstrained optimization problems have been investigated in Toint *et al.* [68] and Gratton *et al.* [69], in order to solve very large-scale trust-region subproblems. Here, some convergence issues related to solutions satisfying both first- and second-order optimality conditions were studied.

MILITARY OPERATIONS RESEARCH SOCIETY (MORS)

TRENA C. LILLY
The Johns Hopkins
University Applied
Physics Laboratory,
Laurel, MD

The Military Operations Research Society (MORS) is a professional society dedicated to promoting excellence in analysis within the national security community through the advancement and application of the interdisciplinary field of operations research to national security issues.

MORS has served the US Department of Defense analytic community for over 40 years. Today, the society also serves other parts of the government concerned with national security matters. Under the sponsorship of the army, navy, air force, marine corps, Office of the Secretary of Defense, the Joint Staff, and the Department of Homeland Security, the objective of MORS is to enhance the quality and effectiveness of operations research (OR) as applied to national security issues.

MORS vision is to “become the recognized leader in advancing the national security analytic community through the advancement and application of the interdisciplinary field of operations research to national security issues, being responsive to our constituents, enabling collaboration and development opportunities, and expanding our membership and disciplines, while maintaining our profession’s heritage.” This vision encompasses all aspects of national security including not only the military but also Homeland Security and the other agencies of government—as well as allies of the United States.

Members of the society include a cross section of professional defense analysts, operators, and managers from government, industry, and academia. Their involvement fosters professional interchange within the

military operations research community, the sharing of insights and information on challenging national security issues, and specific support to decision makers in the many organizations and agencies that address national defense. MORS provides an array of meetings and publications to expose its members to the broad spectrum of thought by distinguished analysts and senior members of our community. In particular, the society provides a unique environment in which classified presentations and discussions can take place with joint service participation and peer criticism from the full range of students, theoreticians, practitioners, and users of military analysis. Throughout its activities, the society promotes the highest standards of professional methodology, individual excellence, and ethical conduct.

BACKGROUND

The first Military Operations Research Symposium, sponsored by the Office of Naval Research (ONR), Pasadena, was held at Corona Naval Ordnance Laboratory, Corona, California, in August 1957. The subject of the meeting was Air Defense, and 83 scientists attended. This and subsequent early meetings were oriented to fulfill the needs of the Operations Research Community on the West Coast. Starting with the Eighth MORS, the symposia became nationally oriented joint service meetings. The first national symposium was the Ninth MORS, held at Fort Monroe, Virginia, in April 1962. From the First through the 10th MORS, there was no formal organization to stage the meetings. They were conducted by ONR–Pasadena with the help of a volunteer steering committee.

Beginning with the eleventh MORS, ONR–Washington assumed supervision and hired a contractor to perform the work in cooperation with a volunteer

executive committee. This arrangement continued until April 1966 during which MORS was incorporated under the laws of Virginia.

Since its incorporation in 1966, MORS has been led by a Board of Directors. The Board of Directors consists of 28 voting members and 2 nonvoting members: the Chief Executive Officer and the Immediate Past President. The board is also led by an Executive Council consisting of the President, the President-Elect, the Immediate Past President, the Vice President for Financial Management, the Vice President for Member and Societal Services, the Secretary of the Society, and the Chief Executive Officer.

Figure 1 shows the PHALANX Newsletter announcement of MORS incorporation.

Table 1 shows the Past Presidents of the Military Operations Research Society.

RECOGNIZING EXCELLENCE AND LONG-TERM CONTRIBUTIONS

MORS is proud of its heritage, as it closely reflects the heritage of operations research in the United States. Since it was incorporated, MORS has recognized and continues to recognize individuals whose contributions continue to promote excellence in the field of OR.

Fellows of the Society

MORS recognizes those individuals who have made long-lasting and significant contributions to the society as *Fellows of the Society*. Fellows are elected for life. Fellows were first elected in 1989 and are elected annually at the December Board of Directors meeting. These individuals represent many of the great minds in the military and national security OR field.

Awards

In direct support of the society's purpose to enhance the quality and effectiveness of national security analysis, MORS annually

presents awards that recognize outstanding individuals in the profession as well as the outstanding work by individuals and teams. These awards include the Wanner Award, the Thomas Award, the Walker Award, and the Hughes Award.

The Wanner Award. Named after Vance R. Wanner, a respected professional who provided enduring value to the military operations research community, this award recognizes individuals for long-term contributions to the profession. The award gives evidence of MORS' belief that OR represents a symbiosis of people and systems, not merely a set of techniques for manipulating data and evaluating results. The award emphasizes that leadership in military OR includes more than mastery of a set of analytic tools. This award, therefore, seeks to identify and recognize members of the profession who have advanced beyond mere excellence in individual achievement and have expanded the application of military OR and raised its standards. This award also gives consideration to the management and leadership of military OR— its direction and control, quality,

applicability, and timeliness. The award is given with the hope that it will inspire members of the military OR community to broaden their scope of participation in the advancement of the profession.

Clayton J. Thomas Award. The Clayton J. Thomas Award recognizes individuals for long-term technical contributions to enhance the analytical capabilities of the profession. This award recognizes outstanding individuals for consistent, sustained technical

contributions to improve the analytical underpinnings of the military OR profession.

John K. Walker, Jr. Award. The John K. Walker, Jr. Award is named in recognition of John K. Walker, Jr., a respected professional, *PHALANX* Editor for 12 years and *PHALANX* Editor Emeritus for 7 years. By his long-term involvement with the MORS, Mr. Walker gave much of enduring value to the military OR community. This award recognizes the author(s) of the technical article judged to be the best such article published in *PHALANX*, the Bulletin of Military Operations Research, during the previous calendar year. This award also emphasizes that *PHALANX* promotes communication among practitioners of military OR that is timely, important, and interesting to the *PHALANX* audience.

Wayne P. Hughes, Jr. Award. The Wayne Pilo Hughes, Jr. Award is named after a former member of the MORS Board of Directors, the 20th MORS President (1985–1986), and a MORS Fellow of the Society (FS) of the First Fellow's Class of 1989. Wayne Hughes served as a distinguished commander, a military analyst, and a Service school educator. Throughout his career, he contributed as a monograph editor and Naval Tactics book author and served as mentor to an enormously long list of Junior Analysts. This award recognizes young analysts who are already making an impact on OR through outstanding publication(s) highlighting their analyses, development of significant new analysis, or the use of research results for solving military problems.

Prizes. MORS annually presents awards in direct support of the society's purpose to enhance the quality and effectiveness of national security analysis through the application of military OR techniques and the improvement of its set of analytical tools. MORS offers the David Rist Prize and the Richard H. Barchi Prize, as well as the Graduate Research Prizes.

David Rist Prize. The David Rist Prize, named after a former member of the MORS Board of Directors, was first awarded in 1965 and is presented to the best study or

other operations research-based efforts, for example, analyses and methodology improvements that influenced major decisions or processes. The objective of the David Rist Prize is to recognize the practical benefits sound OR can have on real-life decision making as well as to provide recognition to OR practitioners whose study/project recommendations were implemented, in order to reward them and to encourage a high degree of excellence in military OR.

Richard H. Barchi Prize. First awarded in 1983, the *Richard H. Barchi Prize* is named for Commander Richard H. Barchi, United States Navy (USN), a former member of the MORS Board of Directors. The objective of the Richard H. Barchi Prize is to provide recognition to authors of the best paper presented at the MORS' annual Symposium, in order to encourage a high degree of excellence in military OR. To be eligible, papers must report on original analysis of methodology developed by the authors, be relevant to problems of military planning, operations, or management and must represent OR or systems analysis in the broadest sense. The papers must be clear, logical, and coherent in structure and should report on completed analysis.

Graduate Research Prize. A Graduate Research Prize for OR students is presented for each graduating class at the US Naval Postgraduate School and the US Air Force Institute of Technology. The prize consists of a \$200 honorarium and a plaque. The prize at the Naval Postgraduate School has been named the Military Operations Research Society Stephen A. Tisdale Prize in honor of LCDR Stephen A. Tisdale, a winner of the Prize who was killed in a military aircraft accident in 1991.

The Graduate Research Prize emphasizes that progress in military OR depends on continuous improvement to a kit of analytic tools. It therefore seeks to identify and recognize members of the profession who have excelled in individual achievement, have expanded the application of military OR techniques and have improved its set of analytical tools. It also gives consideration to the development of the analytical underpinnings of military OR. The award is given to inspire members of the military OR community to continue technical, in-depth participation in the advancement of the profession by emphasizing the analytical foundations of the profession.

MORS MEETINGS

MORS Symposium

For over 45 years, the annual MORS Symposium has been a premier opportunity

MILITARY APPLICATIONS SECTION

Newsletter
Vol. 1 No. 3 May 1966

MAS Activity at ORSA Meeting

THE MILITARY APPLICATIONS SECTION sponsored five major sessions at the 29th National Meeting of the Operations Research Society of America in Santa Monica, California, May 18 to 20. The subjects of the five sessions were: I. Air Warfare, chairman George L. Arnold of Lockheed California; II. Military Operations Research--Where should it be done?, chairman John B. Lathrop, Lockheed California; III. Logistics, chairman Walter R. Deemer, U.S. Arms Control and Disarmament Agency; IV. Tactics, chairman Carroll L. Zimmerman, Consultant; V. General Developments, chairman C. J. Ancker, Jr., System Development Corporation. In addition the Military Applications Section cosponsored two sessions with the Cost Effectiveness Section. One was a panel on measuring the effectiveness of our military and political effort in Viet Nam and the second, chaired by Robert L. Perry of RAND, was on the subject, Can Cost-Effectiveness of Military R & D be Measured?

Reviews of some of these sessions will be found on pp. 10 and 11.

MORS Meets, Takes Society Status

IN VIEW OF THE maturity and position of the Military Operations Research Symposia in the professional community, the MORS Executive Committee decided at its meeting of 22 May 1966 to incorporate as a non-profit professional society under the name of Military Operations Research Society. In the past, the MORS have been organized by Marshall Yovits, ONR, through a contract with the Operational Logic Corporation and with the advice of the MORS Executive Committee. It is expected that in the future ONR will contract with the Society to conduct symposia similar to those previously conducted by ONR.

The 17th Symposium met in Monterey, California, from 23 through 25 May 1966. There were 578 attendees, 82 of whom also attended the ORSA meeting the previous week in Santa Monica. During the symposium the MORS Executive Committee elected the following officers:

President: Howard Berger
First Vice President: Robert J. Miller
Second Vice President: William J. Nemerever
Secretary-Treasurer: John G. Honig

Tandem ORSA and MORS Meetings

THE NATIONAL MEETINGS of the Operations Research Society of America and of the Military Operations Research Society were held back-to-back on the West Coast this May. The ORSA meeting was held at Santa Monica, May 18-20, ending on a Friday. The MORS was held at Monterey, California, May 23-25, starting on a Monday. Many persons attended both meetings. The intervening weekend was used to good advantage by some for a pleasant drive up the coast to Monterey, or for a happy time at San Francisco. Eighty two of the 578 MORS attendees had also attended the ORSA meeting.

Planning is now well underway for a similar arrangement on the East Coast. The 30th National Meeting of ORSA will be held October 17-19 in Durham, North Carolina. The chairman is George E. Nicholson, Jr., of the University of North Carolina. MAS will

See *Tandem*, p. 2

The following new members of the Executive Committee were elected at the same time:

Lloyd F. Bell
Alfred Blumstein
Seth Bonder
Melvin Dresher
Joseph H. Engel
Murray Greyson
Laurence A. Harvey
Alexander L. Slafkosky

Under the new By-Laws of the Society, Lewis A. Leake will serve as the Prior Past President on the Executive Council along with the newly elected officers.

Now that MORS has emerged as a full-fledged professional society the Executive Committee feels that it is an appropriate time to review the operation of the symposia and to consider what long-range relationships should exist between ORSA and MORS. In order

See *Society*, p. 3

Figure 2. One of the first PHALANX publications.

for the national security community to exchange information, examine research and discuss critical national security topics. Held in notable locations, the Symposium gathers over a thousand OR

professionals from military, government, industry and academic ranks to share best practices and take advantage of peer-to-peer networking in a supportive environment.

Figure 3. First PHALANX published in 1974 in conjunction with MORS.

Special Meetings

MORS Special Meetings are convened five or more times a year to investigate critical national security topics. The purpose of the meetings is to explore methodology, examine an issue and develop potential recommendations. Participants have a unique, high

level opportunity to explore the leading edge with their peers and influence the course of research.

Education and Professional Development Colloquium

The MORS Education and Professional Development Colloquium brings together

Figure 4. PHALANX 2012.

students, academics and professionals from the OR community to meet, share and learn about current trends in OR education and professional development, as well as new research emerging from OR programs at the academies, universities and colleges.

The colloquium helps to prepare the next generation of national security analysts for the challenges of the profession with the guidance of experienced analysts.

PUBLICATIONS

MORS publications provide sources of unique and vital information and insight on the business and science of OR. These publications include PHALANX, the MORS Journal, Books, and unclassified reports from Symposia and Special Meetings. MORS publications provide a foundational “body of knowledge,” as well as information on trends and the leading edge of research.

Military Operations Research

A Journal of the Military Operations Research Society

Figure 5. MOR Journal.

PHALANX

Beginning in 1974, *PHALANX*, the Bulletin of Military Operations Research was published quarterly by the Military Applications Section of the Institute for Operations Research and Management Sciences (INFORMS/MAS) jointly with MORS. *PHALANX* provides a cross section of important current research, meetings summaries, MORS news and informative oral histories.

Figure 2 shows the first *PHALANX* publication.

Figure 3 shows the first *PHALANX* published in 1974 in conjunction with MORS.

Figure 4 shows the current edition of *PHALANX*.

Military Operations Research (MORS) Journal

Military Operations Research is a peer-reviewed journal of high academic quality.

Figure 6. MORS Publication “Methods for Conducting Military Operational Analysis”.

The MORS Journal publishes articles that describe OR methodologies and theories used in key military applications. Of particular interest are papers that present case studies showing innovative OR applications,

applications of OR to major policy issues, introduce interesting new problem areas, highlight educational issues, and document the history of military OR. Figure 5 shows the MOR Journal.

Figure 7. MORS Heritage Series Publication “Analysis for Military Decisions”.

MORS Books

MORS books are a valuable source of reference material on OR methods, models and techniques, as well as informative and useful historic accounts.

Figure 6 highlights the MORS publication “*Methods for Conducting Military Operational Analysis*”.

Figure 7 highlights the MORS Heritage Series publication “*Analysis for Military Decisions*”.

Figure 8. MORS Publication “Military Modeling for Decision Making”.

Figure 8 highlights the MORS publication “*Military Modeling for Decision Making*”.

SUMMARY

The Military Operations Research Society (MORS) will continue to support the national security analytic community through the advancement and application of the interdisciplinary field of OR to national security issues, by being responsive to its constituents, enabling collaboration and professional development opportunities, and expanding its membership and disciplines, while maintaining the profession’s heritage.

MILP SOFTWARE

JEFFREY T. LINDEROTH

Bologna, Italy

INTRODUCTION

This article discusses software for solving a general *mixed-integer linear program* (MILP) in the form

$$\min\{c^T x : Ax \geq b, x \geq 0, x_j \in \mathbb{Z} \forall j \in I\}. \quad (1)$$

The algorithmic approach relies on the iterative solution, through general-purpose techniques, of the *linear programming* (LP) relaxation

$$\min\{c^T x : Ax \geq b, x \geq 0\}, \quad (2)$$

that is, the same as problem (1) above but the integrality requirement on the x variables in the set I has been dropped. We denote an optimal solution of problem (2) as x^* . The reason for dropping such constraints is that MILP is NP-hard while LP is polynomially solvable and general-purpose techniques for its solution are efficient in practice.

The articles titled ***Simplex-Based LP Solvers*** and ***Interior-Point Linear Programming Solvers*** cover state-of-the-art LP techniques and solvers, while in the present article we concentrate on the basic characteristics and components of current—commercial and noncommercial—MILP solvers.

Roughly speaking, using the LP computation as a tool, MILP solvers integrate

the *branch-and-bound* and the *cutting-plane* algorithms through variations of the general *branch-and-cut* scheme proposed by Padberg and Rinaldi [1] in the context of the *traveling salesman problem* (TSP). The articles titled ***Mathematical Programming Approaches to the Traveling Salesman Problem*** and ***Branch and Cut*** discuss, in detail, approaches for the TSP and the branch-and-cut approach in its full generality, respectively. Nevertheless, with the aim of giving a quick overview and fixing the notation, we briefly discuss in the following both the branch-and-bound and the cutting-plane algorithms.

The Branch-and-Bound Algorithm

In its basic version the branch-and-bound algorithm [2] iteratively partitions the solution space into sub-MILPs (the children nodes), which have the same theoretical complexity of the originating MILP (the father node or the root node if it is the initial MILP). Usually, for MILP solvers, the branching creates two children by rounding of the solution of the LP relaxation value of a fractional variable, say x_j , constrained to be integral

$$x_j \leq \lfloor x_j^* \rfloor \quad \vee \quad x_j \geq \lfloor x_j^* \rfloor + 1. \quad (3)$$

The two children above are often referred to as *left* (or “down”) branch and *right* (or “up”) branch, respectively. On each of the sub-MILPs the integrality requirement on the variables $x_j, \forall j \in I$ is relaxed and the LP relaxation is solved. Despite the theoretical complexity, the sub-MILPs become smaller and smaller because of the partition mechanism (basically some of the decisions are taken) and eventually the LP relaxation is directly integral for all variables in I . In addition, the LP relaxation is solved at every node to decide if the node itself is worthwhile to be further partitioned: if the LP relaxation value is already not smaller than the best feasible solution encountered so far, called

incumbent, the node can safely be fathomed because none of its children will yield a better solution than the incumbent. Finally, a node is also fathomed if its LP relaxation is infeasible.

The Cutting-Plane Algorithm

Any MILP can be solved without branching by simply finding its “right” LP description; more precisely, the *convex hull* of its (mixed-)integer solutions [3]. In order to do that, one has to iteratively solve the so-called *separation problem*

Given a feasible solution x^* of the LP relaxation (2) which is not feasible for the MILP (1), find a linear inequality $\alpha^T x \geq \alpha_0$ which is valid for system (1), that is, satisfied by all feasible solutions $\bar{x}$ of the system (1), while it is violated by x^* , that is, $\alpha^T x^* < \alpha_0$.

Any inequality solving the separation problem is called a *cutting plane* (or a *cut*, for short) and has the effect of tightening the LP relaxation to better approximate the convex hull.

Gomory [3] has given an algorithm that converges in a finite number of iterations for pure *integer linear programming* (ILP)¹, with integer data. Such an algorithm solves the separation problem above in an efficient and elegant manner in the special case in which x^* is an optimal basis of the LP relaxation. No algorithm of this kind is known for MILPs.

The idea behind integrating the two algorithms above is that LP relaxations (2) do not naturally well approximate, in general, the convex hull of (mixed-)integer solutions of MILPs (1). Thus, some extra work to devise a better approximation by tightening any relaxation with additional linear inequalities (cutting planes) increases the chances that fewer nodes in the search tree are needed. On the other hand, pure cutting-plane algorithms show, in general, a slow convergence and the addition of too many cuts can lead to very large LPs, which in turn present

numerical difficulties for the solvers. The branch-and-cut algorithm has been proven to be very effective initially for combinatorial optimization problems (like TSP) with special-purpose cuts based on a polyhedral analysis and later on in the general MILP context.

This article is split into two parts. In the section titled “Basic Components of MILP Solvers,” we discuss the basic components of nowadays MILP solvers. In the section titled “MILP Software,” we list the available, commercial and noncommercial, solvers with special emphasis to their flexibility in terms of being usable within different modeling and development environments.

Some of the solvers that are discussed in the above-mentioned section have their own modeling environment and modeling language. Moreover, a recent trend for MILP software producers has been adding additional capabilities to the solvers, like that of solving some special classes of (mixed-integer) nonlinear programs (MINLPs). Although modeling languages and the possibility of solving MINLPs within an MILP enumerative framework are very interesting topics, they are not discussed in detail in this article. The reader is referred to the article titled for modeling environments and languages and to the articles **Conic Optimization Software**; **Software for Nonlinearly Constrained Optimization**; and **MINLP Solver Software** for NLP and MINLP software.

BASIC COMPONENTS OF MILP SOLVERS

Nowadays MILP solvers incorporate key ideas developed during the first 50 years of integer programming. In the next sections, we discuss the main ingredients in a concise way. For more details, the reader is referred to Achterberg [4] and Lodi [5] and to many articles in this encyclopedia.

Presolving

In the presolving (often called *preprocessing*) phase, the solver tries to detect certain changes in the input that will probably lead to a better performance of the solution process.

¹ILPs are the special case of MILPs where all variables belong to I , that is, are constrained to be integers.

This is generally done without “changing” the set of optimal solutions of the problem at hand² and it affects two main situations.

On the one side, it is often the case that MILP models can be improved with respect to their given formulation³ by either removing redundant information (variables or constraints) or strengthening the variable bounds generally by exploiting the integrality of variables in I . Modern MILP solvers have the capability of cleaning up the models so as to create a presolved instance associated with the original one on which the MILP technology is then applied. The advantage is twofold: first the LP relaxation becomes smaller (then, generally, quicker to solve), and second such relaxations become stronger, that is, better approximating the convex hull of (mixed-)integer solutions. Finally, more sophisticated presolve mechanisms are also able to discover important implications and substructures that might be of fundamental importance later on in the computation for both branching purposes and cutting-plane generation.

For a detailed overview of presolving techniques, the reader is referred to Savelsbergh [7] and Martin [8].

Cutting-Plane Generation

The importance of cutting planes has been already pointed out in the introduction: without iteratively strengthening the approximation of the convex hull of (mixed-)integer solutions provided by the LP relaxation, current enumerative schemes would fail in solving difficult MILP instances.

The arsenal of separation algorithms has been continuously enlarged over the years. A large group of cuts, with strong relationship among each other, includes

Chvátal–Gomory cuts, Gomory mixed-integer cuts, mixed-integer rounding cuts, $\{0, \frac{1}{2}\}$ cuts, lift-and-project cuts, and split cuts. Essentially, all these inequalities are obtained by applying a disjunctive argument, exploiting the integrality, on an integer or mixed-integer set given by a single constraint generally derived by aggregating many others. This group of cuts is presented in a brilliant and unified way by Cornuéjols [9].

Among the more “combinatorial” cutting planes, that is, those whose derivation is not directly associated with disjunctions on the integer variables, certainly the most used and useful ones are clique and cover inequalities. Cover inequalities played a fundamental role in pioneering MILP solvers [10,11].

These classes of inequalities are discussed in the sections titled “Cutting Planes” and “Automatic Convexification” in this encyclopedia.

Sophisticated Branching Strategies

The branching mechanism introduced in the introduction section requires to take two independent and important decisions at any step: node and variable selections.

Node Selection. This is very classical: one extreme is the so-called *best-bound first* strategy in which one always considers the most promising node, that is, the one with the smallest LP value, while the other extreme is *depth first* where one goes deeper in the tree and starts backtracking only once a node is fathomed, that is, it is either (mixed-)integer feasible, or LP infeasible or it has a lower bound not better (smaller) than the incumbent. The pros and cons of each strategy are well known: the former explores a less number of nodes but generally maintains a larger tree in terms of memory while the latter might need to explore a very large number of nodes. Modern software packages, typically, by default employ a hybrid of these two search techniques.

Variable Selection. The variable selection problem is the one of the methods to decide how to partition the current node, that is, on which variable to branch on in order to create the two children. For a long time, a

²In fact, the set of optimal solutions might change due to presolve, for example, in the case of symmetry breaking reductions; see Margot [6] and the article titled *Heuristics in Mixed Integer Programming*.

³This is especially true for models originated from real-world applications and created by using modeling languages.

classical choice has been branching on the most fractional variable, that is, in the 0–1 case the closest to 0.5. This rule has been computationally shown [12] to be worse than a random selection. However, it is of course cheap to evaluate. In order to devise stronger criteria one has to do much more work. The extreme is the so-called *strong branching* technique [13], in which at any node one has to tentatively branch on each fractional variable and select the one on which the increase in the bound on the left branch times the one on the right branch is maximum. In such a version strong branching is clearly impractical but its computational effort can be limited by (i) defining a small candidate set of variables to branch on and (ii) heuristically solving each LP by limiting *a priori* the number of simplex pivots to be performed. Other sophisticated techniques are *pseudocost branching* [14] and, the recently introduced *reliability branching* [12].

Primal Heuristics

Although primal heuristics have been part of the arsenal of the MILP solvers, almost since the beginning, only recently have they become a crucial component. This is likely in response to user demands. Solving an MILP to optimality might be less important in application than providing “good” solutions within short computing times.

The article titled *Heuristics in Mixed Integer Programming* is devoted to heuristics for mixed-integer programming (MIP), and two main classes of primal heuristics are considered.

On the one hand, at the root node and often at the internal nodes of the search tree, the solvers apply heuristics with the aim of converting a solution of the LP relaxation into an integer feasible solution. This is obtained through *rounding* an LP solution either component by component (without any backtracking or additional LP solve) or by *diving*, that is, rounding one or more variables and solving the LP relaxation again, iteratively. The most successful algorithm falling in this category is the *feasibility pump* heuristic proposed (for 0–1 MILPs) by Fischetti *et al.* [15].

On the other hand, once one or more feasible solutions are available, *improvement* heuristics are executed to improve the quality of the current incumbent solution. These heuristics are usually local search methods and we have recently seen a variety of algorithms which solve sub-MILPs for exploring the neighborhood of the incumbent or of a set of solutions. When these sub-MILPs are solved in a general-purpose manner, that is, through a nested call to an MILP solver, this is referred to as *MIPping* [16]. The most successful algorithms falling in this category are *local branching* by Fischetti and Lodi [17] and *relaxation induced neighborhood search* by Danna *et al.* [18].

Parallel Implementation

The branch-and-bound algorithm is a natural one to parallelize, as nodes of the search tree may be independently processed. A long body of research and implementations of parallel branch-and-bound are outlined in the survey [19]. The two types of parallel integer programming research can be loosely categorized based on the type of parallel computing architecture used. Distributed-memory architectures rely on message passing to communicate results of the algorithm. Shared-memory computers communicate information among CPUs by reading from and writing to a common memory pool.

Eckstein [20,21] was among the first to write an industrial strength parallel branch-and-bound code for general MILP. Over the past few years, there has been an emergence of *multicore* computer architectures, such that nearly all modern CPUs contain more than one unit on which computation may be performed. MILP software has followed this trend, so that many of the below surveyed packages have the ability to run multiple threads of computation, thus making use of multiple cores. For many applications, an important characteristic of the branch-and-bound algorithm is to be able to produce solutions that are *reproducible*. In parallel branch-and-bound, it is well known that the *order* in which node computations are completed can have a significant impact on performance, and often

lead to anomalous behavior [22]. An (often) undesirable consequence of this is that users can run the same instance, with the same parameter settings, and achieve very different results in terms of nodes evaluated and CPU time. To combat this undesirable behavior, modern (shared-memory-based) MILP software has introduced appropriate synchronization points in the algorithm to ensure reproducible behavior in a parallel environment. Some overhead is introduced by these synchronization mechanisms.

MILP SOFTWARE

In this section we concentrate on MILP software by first presenting a historical perspective and briefly discussing the issue of the user interface. Then, we review the main characteristics of both commercial and non-commercial MILP software packages.

Historical Perspective

The earliest commercial grade implementations of branch-and-bound algorithms for solving MILP were done by Beale and Small [23]. For a historical perspective of the development and features of early MILP software packages, such as UMPIRE, SCICONIC, and MPSX/370, the reader is referred to the article of Forrest and Tomlin [24]. These early MILP software packages developed many effective branching and node selection techniques, some of which are still in use today. A major step forward in MILP solution technology occurred in the works of Crowder *et al.* [10] and Van Roy and Wolsey [11]. These papers introduced many of the preprocessing- and structure-specific cutting-plane techniques in use today. Another important work from a computational perspective was by Balas *et al.* [25], which demonstrated that the inequalities of Gomory [26] could be effectively used as cutting planes in a branch-and-cut procedure.

Modern MILP codes synthesized many of the ideas present in the literature, taking the best points of these works and engineering them into commercial-grade software packages. The article of Bixby and Rothberg [27] offers a nice historical exposition

of how MILP software improved by orders of magnitude over a period of a decade, starting in the late 1990s.

User Interfaces

An important aspect of the design of software for solving MILPs is the user interface. The range of purposes for MILP software is quite large, so it stands to reason that the number of user interface types is also large. In general, users may wish to solve MILPs using the solver as a “black box,” they may wish to call the software from a third party package, or they may wish to embed the solver into custom applications, which would require software to have a callable library. Often, the user may wish to adapt certain aspects of the algorithm. For instance, the user may wish to provide a custom branching rule or problem-specific valid inequalities. The customization is generally accomplished either through the use of language callback functions or through an abstract interface wherein the user must derive certain base classes and override default implementations for the desired functions. Nearly all of the below surveyed software packages have stand-alone executables, callable libraries, and allow the user to customize the branch-and-bound algorithm to varying degrees.

MILP Software Packages

Any review of software features is inherently limited by the temporal nature of software itself. In fact, algorithmic advances in the field of computational integer programming, many previously described in this article, can quickly render obsolete MILP software that was once state of the art. Here, we give a brief overview of what are the most widely used MILP software packages at the time of publication. Hans Mittelmann has for many years run independent benchmarks of MILP software, and been publishing the results. In general, the commercial software significantly outperforms noncommercial software on the instances in the Mittelmann suite, but it is difficult to draw strong conclusions about the relative performance of different commercial systems. Results of these benchmarks can be found

at <http://plato.asu.edu/ftp/milpf.html> and <http://plato.asu.edu/ftp/milpc.html>. Many of these solvers are available for use free of charge on the NEOS server website <http://www-neos.mcs.anl.gov>.

Commercial Software Packages. Unsurprisingly, exact implementation details of specific commercial MILP software packages are not known, as revealing such details would be a competitive disadvantage. In this article, information from the various software user manuals was used to compile features specific to each package. Further, it is impossible to detail all features of a software package, so we focus on those features that are, in the opinion of the authors, particularly noteworthy. Many of the commercial software packages listed here have free or limited cost licensing options available for academic users.

CPLEX

Version: 12.2

Website: <http://www-01.ibm.com/software/integration/optimization/cplex-optimizer/>

Interfaces: C, C++, Java, .NET, Matlab, Python, Microsoft Excel

CPLEX is a commercial MILP software package owned and distributed by IBM. The branch-and-cut algorithm contains a full suite of presolving techniques, cutting planes, search strategies, and heuristic techniques for finding feasible solutions. A special search algorithm in CPLEX, called *dynamic search*, can be used instead of traditional branch-and-cut. CPLEX also includes a *mipemphasis* metaparameter that adjusts many algorithmic parameters simultaneously to help users achieve a high-level goal. CPLEX contains facilities for automatically tuning MILP algorithm parameters for a particular class of instances. CPLEX may parallelize the branch-and-bound search using multiple threads in either a deterministic or nondeterministic manner. A final notable feature of CPLEX is its ability to enumerate multiple solutions that are close to

optimality and store them in a *solution pool*.

Gurobi

Version: 3.0

Website: www.gurobi.com

Interfaces: C, C++, Java, Python, .NET, Matlab

Gurobi Optimizer contains a relatively new MILP solver that was built from scratch to exploit modern multicore processing technology. Gurobi contains all advanced algorithmic features, including a variety of cutting planes, heuristics, and search techniques. Notable features of Gurobi include an *MIPFocus* metaparameter that simultaneously controls many algorithmic parameters to achieve the desired goal. Gurobi may execute the branch-and-bound algorithm using multiple computational threads. The parallel search is done in a deterministic manner. The Gurobi interactive shell is implemented as a set of extensions to the Python shell. Gurobi is also available “on demand” using the Amazon Elastic Compute Cloud.

LINDO

Version: 6.1

Website: www.lindo.com

Interfaces: C, Visual Basic, Matlab, Ox

LINDO Systems offers an MILP solver as part of its LINDO API. The MILP solver offers 15 different types of cutting planes, 6 different node selection rules, and a variety of preprocessing techniques and branching rules.

Mosek

Version: 6.0

Website: www.mosek.com

Interfaces: C, C++, Java, .NET, Python

MOSEK ApS is a company specializing in generic mathematical optimization software, and their suite of software includes a solver for MILP. The solver has 6 node selection rules, 11 types of cutting planes, the feasibility pump, and other heuristics, as well

as advanced branching methodologies such as strong branching. Mosek is available for use, through a GAMS interface, on the NEOS server.

XPRESS-MP

Version: 7.0

Version: <http://www.fico.com/en/Products/DMTools/xpress-overview/Pages/Xpress-Optimizer.aspx>

Interfaces: C, C++, Java, .NET, VBA

FICO Xpress Optimization Suite 7 offers a branch-and-cut-based software for solving MILP. XPRESS-MP offers many advanced cutting planes, including an effective implementation of lift-and-project cuts [28]. Modern preprocessing, heuristic, and branching techniques are also available. A unique feature of XPRESS-MP is that it offers an option to branch into general (split) disjunctions, or to search for special structures on which to branch. XPRESS-MP has features to enumerate multiple feasible solutions, and also to tune algorithmic parameters. XPRESS-MP is available for use, with three different input formats, on the NEOS server.

Noncommercial MILP Packages. Here, we give a cursory description of the most popular noncommercial MILP software packages. The paper of Linderoth and Ralphs [29] contains a more in-depth treatment of noncommercial software packages.

BLIS

License: Common Public License

Version: 0.91

Website: <https://projects.coin-or.org/CHiPPS>

Language: C++

BLIS is an open-source MILP solver available as part of the COIN-OR project. It is built on top of the COIN-OR high-performance parallel search (CHiPPS) framework, so it has been designed to run on distributed-memory platforms (one of the few available MILP software packages with this feature). Linear programs are solved using the COIN-OR

linear programming (Clp) solver, and cutting planes from the COIN cut generation library (CGL) are used.

CBC

License: Common Public License

Version: 2.5

Website: <https://projects.coin-or.org/Cbc>

Language: C++

CBC is an open-source MILP solver distributed under the COIN-OR project. It is built from many COIN components, including Clp and CGL. It is available both as a library and a stand-alone solver. CBC may be parallelized using shared-memory parallelism, and there are a large number of examples demonstrating its use. CBC is available for use on the NEOS server.

GLPK

License: GNU General Public License (GPL)

Version: 4.44

Website: <http://www.gnu.org/software/glpk/>

Language: C

GLPK is the GNU LP kit, a set of subroutines comprising a callable library and black box solver for MILP. The software distinguishes itself by being available under the GNU GPL and through the large number of community-built interfaces available for its use. GLPK is available for use, though a GAMS interface, on the NEOS server.

lp_solve

License: GNU lesser general public license (LGPL)

Version: 5.5

Website: <http://lpsolve.sourceforge.net/5.5/>

Language: C

The software lp_solve is an open-source linear and integer programming solver. There are a large number of interfaces available through which lp_solve can be used, including Java, AMPL, MATLAB, O-Matrix,

Sysquake, Scilab, Octave, Freemat, Euler, Python, Sage, PHP, and R.

MINTO

License: Given as library only

Version: 3.1

Website: <http://coral.ie.lehigh.edu/minto/>

Language: C

MINTO (Mixed INTeget Optimizer) is a black box solver and solver framework for MILP. MINTO is available only in library form. MINTO relies on external software to solve the LP relaxations that arise during the algorithm. Primary development of the software was done in the 1990s. The code was noteworthy at that time for a dynamic preprocessing engine [30] and effective lifted cover inequalities [31]. MINTO is available for use, through an AMPL interface, on the NEOS server.

SCIP

License: ZIB Academic License

Version: 1.2

Website: <http://scip.zib.de/>

Language: C

SCIP is an MILP software package developed and distributed by a team of researchers at Konrad-Zuse-Zentrum für Informationstechnik Berlin (ZIB). SCIP is also a framework for constraint integer programming and branch-cut-and-price, allowing the user significant control of the algorithm. Development of SCIP was awarded the Beale Orchard Hayes Prize in 2009 [32]. Current benchmarks indicate that SCIP is likely the fastest noncommercial MILP solver. Other references for SCIP include the work of Achterberg [33] and Achterberg *et al.* [34]. SCIP is available for use, through a variety of interfaces, on the NEOS server.

SYMPHONY

License: Common Public License

Version: 5.2

Website: <http://www.coin-or.org/SYMPHONY/index.htm>

Language: C

SYMPHONY is a black box solver and callable library for MILPs. The core solution methodology of SYMPHONY is a customizable branch, cut, and price algorithm that can be executed sequentially or in parallel [35]. SYMPHONY calls on several other open-source libraries for specific functionality, including COIN-OR's CGL and Clp. There are several unique features of SYMPHONY that are worth mentioning. First, SYMPHONY contains implementation of an algorithm for solving bicriteria MILPs and methods for approximating the set of Pareto outcomes [36]. SYMPHONY also contains functions for local sensitivity analysis [37]. Second, SYMPHONY has the capability to warm start the branch-and-bound process from a previously calculated branch-and-bound tree, even after modifying the problem data. The work by Ralphs and Guzelsoy [38] gives an overview of the SYMPHONY callable library. SYMPHONY is available for use via MPS files on the NEOS server.

CONCLUSIONS

As decision processes become increasingly complex, the need for formal tools to aid in both planning and operation of the underlying system becomes more important. Many disciplines have embraced the use of optimization as a central tool to enhance the quality of decisions made. A large fraction of the models used in commercial settings are MILPs. Powerful, reliable, and flexible software systems (both commercial and noncommercial) are a key component of this broad-based acceptance. The field of MILP and computational aspects therein remain an active area of research. Given the high commercial penetration of MILP planning models, undoubtedly future research advances will find themselves implemented in software.

INTRODUCTION

Network flows is a problem domain that lies on the cusp between several fields of inquiry, including applied mathematics, computer science, engineering, management, and operations research [1]. The minimum cost flow problem is a fundamental network flow problem. The objective of this problem is to send units of a good that reside at one or more points in a network (sources or supplies) with arc capacities, to one or more other points in the network (sinks or demands), while incurring minimum cost. All other network flow problems such as the shortest path problem, maximum flow problem, assignment problem, and transportation problem can be viewed as special cases of the minimum cost flow problem. In this article, we define the minimum cost flow problem, outline some of its applications, and describe three algorithmic approaches for solving it, namely (i) the cycle canceling algorithm; (ii) the successive shortest path algorithm; and (iii) the network simplex algorithm. These algorithms are iterative improvement algorithms that start with a flow and improve it until optimality conditions are met.

Let $G = (N, A)$ be a directed network with a cost per unit flow c_{ij} and a capacity u_{ij} associated with every arc $(i, j) \in A$. For each node $i \in N$, $b(i)$ indicates its supply or demand depending upon whether $b(i) > 0$ (supply) or $b(i) < 0$ (demand). Let decision variable x_{ij} denote the flow on arc $(i, j) \in A$.

Then, the minimum cost flow problem is mathematically formulated below.

$$\begin{aligned} \text{Minimize } z = & \sum_{(i,j) \in A} c_{ij} x_{ij} \\ & \sum_{\{j:(i,j) \in A\}} x_{ij} - \sum_{\{j:(j,i) \in A\}} x_{ji} = b(i) \\ & \text{for all } i \in N \\ & 0 \leq x_{ij} \leq u_{ij}, \text{ for all } (i,j) \in A. \end{aligned}$$

The first set of constraints ensures the balance of flows at each node and is called the *flow balance constraint*. The second set of constraints establishes lower and upper bounds on the flow on each arc and is called the *flow bound constraint*. Let C denote the largest magnitude of any arc cost and U denote the largest magnitude of any supply/demand or finite arc capacities. We assume that the lower bounds on arc flows are all zero. Let n denote the number of nodes and m the number of arcs. We assume that all data (cost, supply/demand, and capacity) is integral, the network is directed, $\sum_{i \in N} b(i) = 0$, and all arc costs are nonnegative. All these assumptions can be made without loss of generality, because a minimum cost flow problem which violates any of these conditions can be transformed to the standard form [1]. Our algorithms rely on the concept of residual networks. The residual network $G(x)$ corresponding to a flow x is defined as follows. We replace each arc $(i, j) \in A$ by two arcs (i, j) and (j, i) . The arc (i, j) has cost c_{ij} and residual capacity $r_{ij} = u_{ij} - x_{ij}$, and the arc (j, i) has cost $c_{ji} = -c_{ij}$ and residual capacity $r_{ji} = x_{ij}$. $G(x)$ only contains arcs with positive residual capacity.

The minimum cost flow problem has been extensively studied by researchers. Jewell [2], Iri [3], and Busaker and Gowen [4] independently developed the successive shortest path algorithm. Their algorithm solves the minimum cost flow problem as a sequence of shortest path problems with arbitrary arc lengths. Subsequently, Tomizava [5] and Edmonds and Karp [6] observed that if the

computations use node potentials, then it is possible to implement these algorithms so that the shortest path problems have nonnegative arc lengths; this makes the successive shortest path algorithm more efficient. Ford and Fulkerson [7] developed the primal-dual algorithm, and Klein [8] developed the cycle canceling algorithm for the minimum cost flow problem. Three polynomial-time implementations of the cycle canceling algorithm are due to (i) Ref. 9, which modifies an algorithm by Weintraub [10] and augments flow along (negative) cycles with the maximum possible improvement; (ii) Ref. 11, which augments flow along minimum mean cost (negative) cycles; and (iii) Ref. 12, which augments flow along minimum ratio cycles.

The minimum cost flow problem can also be viewed as a special case of the linear programming problem, and therefore the simplex algorithm for linear programming can be used to solve it. The simplex algorithm for the linear programming problem was specialized to develop the network simplex algorithm for the minimum cost flow problem. Efficient manipulation of spanning trees is crucial to the efficacy of the network simplex algorithm. Johnson [13] suggested the first tree-manipulating data structure for implementing the network simplex algorithm for the minimum cost flow problem. Degeneracy is another problem that was encountered while using the network simplex algorithm. Experience with solving minimum cost flow problems established that for certain classes of problems, more than 90% of the pivots in the network simplex algorithm can be degenerate. Cunningham [14], and Barr *et al.* [15,16] proposed the strongly feasible spanning-tree basis that led to improvements on this front. Computational experiences showed that maintaining a strongly feasible spanning-tree basis substantially reduces the number of degenerate pivots. On the theoretical front, Orlin [17] showed that for integer data, an implementation of the network simplex algorithm that maintains a strongly feasible basis performs $O(nmCU)$ pivots when used with any arbitrary pricing strategy, and $O(nmC \log(mCU))$ pivots when

used with Dantzig's pricing strategy. A polynomial-time implementation remained elusive to researchers until Orlin [18] developed an $O(\min(n^2m \log nC, n^2m^2 \log n))$ time algorithm.

The first strongly polynomial-time minimum cost flow algorithm is attributed to Tardos [19]. Subsequently, several researchers [11,20–26] developed other strongly polynomial-time algorithms. Currently, the fastest strongly polynomial-time algorithm is due to Orlin [24]. His enhanced capacity scaling algorithm solves the minimum cost flow problem as a sequence of $O(\min(m \log U, m \log n))$ shortest path problems. The best known theoretical time bound for the minimum cost flow problem is $O(\min\{nm \log(n^2/m \log(nC)), nm(\log \log U) \log(nC), (m \log n)(m + n \log n)\})$; the three bounds in this expression are due to Goldberg and Tarjan [23], Ahuja *et al.* [27], and Orlin [24], respectively.

The rest of this article is organized as follows. In the section titled “Applications,” we identify some applications of the minimum cost flow problem; in the subsequent section, we discuss the optimality conditions; and finally in the section titled “Minimum Cost Flow Algorithms,” we describe algorithms to solve the minimum cost flow problem.

APPLICATIONS

Minimum cost flow problems have been extensively applied to solve problems in diverse areas such as transportation, communications, manufacturing, defense, finance, and health care. In this section we describe some of these applications in four different areas and we refer the interested reader to the book by Ahuja *et al.* [1] for a comprehensive review of minimum cost flow applications.

Production Planning Application

While planning for production at a plant, it is preferable to produce in periods when the production costs are lower. On the other hand, this may involve carrying inventory and incurring inventory storage costs. The production planning (or lot-sizing) problem

Figure 1. Production planning application.

determines the optimal production schedule by balancing all these costs. The production planning problem with linear production and inventory carrying costs can be formulated as a minimum cost flow problem.

Let the demand of a single item be $d(i)$ in each of n periods $i = 1, 2, \dots, n$. The demand in period i is fulfilled by either producing x_{0i} in that period and/or by drawing upon inventory $x_{i-1,i}$ from the previous period. Figure 1 shows the minimum cost network for a problem with four periods. Node 0 denotes the source node and has an associated supply of $\sum_{i=1}^n d(i)$, and all other nodes i represent period i and have an associated demand $d(i)$. Node 0 is connected to each demand node i using *production arcs* $(0, i)$; flow on production arcs represent the quantity produced in period i . Each arc $(i-1, i)$ for $i = 2, 3, \dots, n$ is an *inventory arc*; flow on inventory arcs represent the inventory carried from one period to the next. Let c_{ij} be the cost per unit flow on arc (i, j) , and u_{ij} be its capacity. Then, the cost c_{0i} represents the unit cost of production in period i and $c_{i-1,i}$ represents the unit holding cost from period $i-1$ to period i . The capacity u_{0i} represents the production capacity in period i and $u_{i-1,i}$ denotes the inventory carrying capacity from period $i-1$ to i . It is easy to see that the constructed minimum cost flow problem can be used to solve the linear cost dynamic lot-sizing problem.

Teleprocessing Network Design Application

Centralized teleprocessing networks contain several geographically dispersed terminals that need to communicate with a central processing unit (CPU). Each terminal can be connected to the CPU either directly or

Figure 2. Teleprocessing network application.

through a concentrator. A concentrator is capable of merging the data flows from several terminals and sending them to the CPU, and is linked to the CPU by a dedicated high-speed line. Each terminal connection to a concentrator or the CPU has an associated cost of construction. Given the capacity of each concentrator, the teleprocessing network design problem is to determine the minimum cost network configuration that connects each terminal to the CPU.

Let the set of concentrators in the system be C and the set of terminals be T . Each concentrator can serve at most K terminals. Let c_{j0} be the cost of directly connecting terminal j to the CPU and c_{ji} be the cost of connecting terminal j to concentrator i . The minimum cost flow network is constructed as follows. We construct node 0 to represent the CPU. For each concentrator i , we construct a node in the network. We also construct one node for each terminal j . Each terminal j is connected to each concentrator i using arcs (j, i) with cost c_{ji} . Each terminal j is also connected directly to the CPU using arc $(j, 0)$ with cost c_{j0} . Each concentrator i is connected to the CPU using arc $(i, 0)$ with capacity K and zero cost. All the terminals in the network are assigned a supply of unit, and the CPU is assigned a demand of $|T|$ units. Figure 2 shows the minimum cost flow network for an example with four terminals (T1, T2, T3, T4), two concentrators (C1, C2), and one CPU. By solving the constructed minimum cost flow problem, we can identify the minimum cost set of links to construct or the optimal network configuration.

Figure 3. Building evacuation application.

Building Evacuation Application

One of the important considerations while designing a building is the time taken to evacuate in an emergency situation like an earthquake, fire, or bomb threat. Architects typically need to develop an evacuation plan and assess the evacuation time for a particular design. We show how this problem can be modeled as a minimum cost flow problem.

The evacuation network for a building is constructed as follows. The nodes represent locations in the building such as offices, hallways, elevators, staircases, and exits. The arcs represent connections between two locations. The locations in the building that house a significant number of people are the source nodes in the network and the exits are the sinks. The supply of each node is an estimate of the number of people that are likely to be at that location. Each arc has a capacity that represents the maximum number of people that can simultaneously use it at any point in time. We can transform the problem into one with a single source and single sink by using the standard technique of constructing a super-source and a super-sink. In order to correctly account for the travel time on each arc, we consider multiple copies of each node at various points in time using the concept of *time-expanded replica* of a network. For each node i in the original network, we construct p copies $i_1, i_2, \dots, i_p$ representing the node at various times. We also construct arcs (i_k, j_l) to represent a passage that connects location

i and location j if $l - k$ is equal to the travel time on passage (i, j) . This arc represents the potential movement of a person from node i to node j in time $l - k$. The minimum time required to evacuate the building is the smallest index r satisfying the property that the maximum flow from source nodes $s_1, s_2, \dots, s_r$ to the sink nodes $t_1, t_2, \dots, t_r$ is at least a prespecified number of people or the buildings capacity. In Fig. 3, we illustrate the underlying network for a small instance with four locations, travel times as indicated in the figure, and then time expanded over four periods. This problem can be solved using a minimum cost flow algorithm. We refer the interested reader to Ref. 28 for more details.

Distribution Application

Consider a company that needs to manufacture and ship a set of different product models from plants to retailers. Each plant p has an associated capacity of production for each model and each retailer r has a known demand for each model. The company wants to determine how many products of each type should be produced at each plant and the shipping pattern between plants and retailers that minimizes the overall cost of production and transportation.

This problem can be formulated as a minimum cost flow problem. The network contains four types of nodes: (i) plant nodes representing the various plants; (ii) plant-model nodes representing a model made at a plant; (iii) retailer-model nodes representing

the products required by each retailer; (iv) retailer nodes corresponding to the various retailers. The network contains three types of arcs: (i) production arcs connect the plant nodes to the plant-model nodes and the cost of flow on this arc is unit cost of production of the associated model at the plant. The production arcs have an upper bound that represents the capacity of production of the associated model at the plant; (ii) Transportation arcs connect plant-model nodes to retailer-model nodes. The cost of the arc is the total cost of shipping one unit between the associated plant and retailer. (iii) Demand arcs connect the retailer-model nodes and the retailer nodes. The demand arcs have zero cost and a lower bound that represents the demand of the product at that retailer.

The minimum cost flow network is completed by (i) creating a production super-node and connecting it to the plant nodes with arcs of zero cost and infinite capacity; (ii) creating a retailer super-node and connecting the retailer nodes to it with arcs of zero cost and infinite capacity; (iii) creating a feedback arc to connect the retailer super-node to the production super-node. These augmentations ensure that the constructed problem is a minimum cost flow problem in its standard form. In Fig. 4, we give the network for a problem with two plants, two models, and two retailers. Note that the supply and demands of all nodes in the network are zero. Such a problem is a special case of a minimum cost flow problem and is called a *minimum cost circulation problem*. It can be solved using any standard minimum cost flow algorithm.

OPTIMALITY CONDITIONS

Optimality conditions provide us with a simple method to validate whether a feasible solution to a problem is optimal. They also motivate algorithms to solve the underlying optimization problem. Algorithms for the minimum cost flow problem typically start with a flow (or pseudoflow) and iteratively improve it until the optimality conditions for the minimum cost flow is met. In this section, we describe two different yet equivalent optimality conditions for the minimum cost flow problem: (i) negative cycle optimality

conditions; and (ii) reduced cost optimality conditions. In the next section, we describe algorithms which are based on the optimality conditions.

Negative Cycle Optimality Condition

The negative cycle optimality condition is very intuitive in nature and easy to understand. The negative cycle optimality condition states that *a feasible solution to the minimum cost flow problem is optimal if and only if the associated residual network does not contain a negative cost directed cycle*. The if direction is easily established since if the residual network contains a negative cost cycle, then by sending a positive flow on the cycle we obtain a feasible solution with a smaller cost. We refer the interested reader to Ref. 1, p. 307 for a complete proof.

Reduced Cost Optimality Condition

The reduced cost optimality conditions rely on the concept of node potentials. Let $\pi(i)$ be a real number associated with each node $i \in N$. We call $\pi(i)$ the potential of node i . Using these node potentials, we define the reduced cost of arc (i, j) as $c_{ij}(\pi) = c_{ij} - \pi(i) + \pi(j)$. Due to the way in which the reduced costs are defined, the following properties are immediate: (i) for any directed path P between node k and l , $\sum_{(i,j) \in P} c_{ij}(\pi) = \sum_{(i,j) \in P} c_{ij} - \pi(k) + \pi(l)$; (ii) for any directed cycle W , $\sum_{(i,j) \in W} c_{ij}(\pi) = \sum_{(i,j) \in W} c_{ij}$. This property implies that using the reduced costs instead of the actual costs does not change the shortest path between any pair of nodes. Also, if W is a negative cycle with respect to c_{ij} as arc costs, then it is also a negative cycle with respect to $c_{ij}(\pi)$.

The reduced cost optimality conditions are equivalent to the negative cycle optimality conditions. The reduced cost optimality conditions state that *a feasible solution to the minimum cost flow problem is optimal if and only if for some set of node potentials, the reduced cost of all arcs in the residual network are nonnegative*. The proof for correctness is straightforward. Suppose a solution satisfies the reduced cost optimality conditions, then using property (ii) the residual network does not contain a negative cost cycle; hence, the solution satisfies the negative

Figure 4. A distribution application.

cycle optimality condition and is optimal. Conversely, suppose a solution is optimal, then the residual network does not have negative cost cycles. Accordingly, the shortest path distances d from node 1 to all other nodes are well defined. It can be shown that by setting $\pi = -d$, we obtain the desired set of node potentials. We refer to the set of node potentials that satisfy the conditions $c_{ij}(\pi) \geq 0$ for all (i,j) in $G(x)$ as the *optimal node potentials*.

MINIMUM COST FLOW ALGORITHMS

In this section, we discuss three fundamental algorithms to solve the minimum cost flow

problem. All these algorithms start with an initial solution and perform a set of operations repeated until flow feasibility and/or optimality conditions are satisfied.

Cycle Canceling Algorithm

The cycle canceling algorithm is a direct consequence of the negative cycle optimality conditions. This algorithm starts with a feasible flow x and at every iteration it improves the current feasible solution by augmenting flow on a negative cost cycle in $G(x)$. The algorithm terminates when it cannot find any negative cost cycle in $G(x)$. We now formally define the cycle canceling algorithm.

```

algorithm cycle canceling;
begin
  establish a feasible flow  $x$  in the network;
  while  $G(x)$  contains a negative cycle do
    begin
      identify a negative cycle  $W$ ;
      compute  $f = \min\{r_{ij} : (i,j) \in W\}$ ;
      augment  $f$  units of flow in the cycle  $W$  and update  $G(x)$ ;
    end
  end

```

Figure 5. Illustration of the cycle canceling algorithm: (a) initial solution with $z = 16$; (b) negative cost cycle 1-3-4-2-1 in $G(x)$; (c) $G(x)$ after flow augmentation of one unit (contains no negative cost cycle); and (d) optimal solution with $z = 14$.

An interesting corollary of the cycle canceling algorithm is that it proves that when the arc capacities and supply/demands are integers, then the minimum cost flow problem always has an integer optimal flow. Our description of the algorithm is generic in the sense that when there are multiple negative cost cycles, we do not specify the criteria to choose one. Different rules for selecting negative cycles produce different versions of the algorithm, each with different running times.

Consider the running time of the generic version of the cycle canceling algorithm. An initial feasible flow x can be determined by solving a maximum flow problem. Also, each negative cost cycle can be identified in $O(nm)$ time using the label-correcting algorithm for the shortest path problem. Note that mCU is an upper bound on the cost of the initial feasible solution. Also, mCU is a lower bound

on the optimal solution cost. Since each iteration reduces the solution cost by at least one unit (all data is integral), the algorithm runs through $O(mCU)$ iterations. Hence, the algorithm runs in $O(nm^2CU)$ time.

In Fig. 5, we give an example for the cycle canceling algorithm. We start with a feasible solution in Fig. 5(a) with objective function $z = 16$. Next, we identify the residual network corresponding to this solution in Fig. 5(b). This residual network has a negative cost cycle 1-3-4-2-1 with cost -2 (indicated in dotted lines). We augment one unit of flow on this cycle to obtain a better solution with $z = 14$. Next, we update the residual network as shown in Fig. 5(c). The residual network no longer contains a negative cost cycle and the algorithm accordingly terminates. We use the residual network in Fig. 5(c) to obtain the actual optimal flows in Fig. 5(d).

Successive Shortest Path Algorithm

The successive shortest path algorithm is different from the cycle canceling algorithm in the sense that the algorithm maintains a solution that satisfies the optimality conditions and strives for feasibility (the cycle canceling algorithm maintains feasibility and strives for optimality). The algorithm always maintains a solution x that satisfies the flow bound constraints, but may violate the flow balance constraints. We call such a solution a *pseudoflow*. The algorithm starts with zero pseudoflow and repeatedly sends flow on successive shortest paths in $G(x)$ until all the demands have been met. It can be shown that by sending flows on successive shortest paths in the residual network, the algorithm

```

algorithm successive shortest path;
begin
  set  $x = 0$ ;
  while  $x$  is not a flow do
    begin
      select an excess node  $s$  and a deficit node  $t$ ;
      identify a shortest path  $P$  from node  $s$  to node  $t$  in  $G(x)$ ;
      augment maximum possible flow on  $P$  and update  $G(x)$ ;
    end
  end

```

We now consider the running time of the algorithm. Let U be an upper bound on the largest supply of a node. Since each iteration of the algorithm augments at least one unit of flow, the number of flow augmentations is $O(nU)$. Also, every iteration of the algorithm involves solving the shortest path problem; let this take $S(n, m, C)$ time. All other steps in the while loop can be performed in $O(n)$ time. Accordingly, the running time of the algorithm is $O(n U S(n, m, C))$. Note that during the algorithm, the cost of arcs in $G(x)$ can become negative which makes the shortest path problem more difficult to solve than one with nonnegative arc lengths. However, it is possible to use the node potentials to maintain nonnegative arc lengths, which allows us to solve the shortest path problems more efficiently. We refer the interested reader to Ref. 1 for further details.

In Fig. 6, we give an example for the successive shortest path algorithm. We start with a pseudoflow $x = 0$. The shortest path in

always maintains a pseudoflow that satisfies the negative cycle optimality condition (the residual network does not contain a negative cost cycle). Accordingly, whenever the pseudoflow satisfies all the flow balance conditions and becomes a feasible flow, feasibility and optimality are achieved and the algorithm terminates.

For any pseudoflow x , we define the *imbalance* of node i as $e(i) = b(i) - \sum_{j:(i,j) \in A} x_{ij} + \sum_{j:(j,i) \in A} x_{ji}$. If $e(i) > 0$, we refer to $e(i)$ as the *excess* of node i and if $e(i) < 0$, we call $e(i)$ the *deficit* of node i . The residual network $G(x)$ for a pseudoflow x is defined in a similar manner to the residual network for a flow. The successive shortest path algorithm is defined below.

$G(x)$ from the excess node to the deficit node is 1-3-4 with cost 3 as shown in Fig. 6(b). We augment 2 units of flow on 1-3-4 and update the residual network as shown in Fig. 6(c). The shortest path in $G(x)$ from the excess node to the deficit node is 1-2-3-4. We augment 2 units of flow on 1-2-3-4 to obtain the residual network shown in Fig. 6(d). At this point, the excess and deficit are zero and solution is a flow. Accordingly, the algorithm terminates.

Network Simplex Algorithm

The simplex algorithm for solving linear programming problems is perhaps the most powerful algorithm devised for solving constrained optimization problems. Due to the special constraint structure (unimodularity) of the minimum cost flow problem, all extreme point solutions are integral and the problem can be solved as a linear programming problem. However, using the

Figure 6. Illustration of the successive shortest path algorithm: (a) initial solution with $x = 0$, $z = 0$; (b) shortest path 1-3-4 in $G(x)$; (c) $G(x)$ after augmentation of 2 units on 1-3-4; and (d) $G(x)$ after augmentation of 2 units on 1-2-3-4.

generalized simplex method to solve the minimum cost flow problem does not lead to competitive running times when compared to previously discussed combinatorial approaches. In this section, we describe a specialized network adaptation of the simplex method that exploits the network property to solve the minimum cost flow problem efficiently. The network simplex algorithm allows us to perform all the steps in the simplex algorithm directly on the network.

The central concept in the *network simplex algorithm* is the notion of spanning-tree solutions.

In a spanning-tree solution, the flows on all arcs which are not in the spanning tree are fixed to either zero or the arc's flow capacity (*non-tree arcs*). Once this is done, the flow on all other arcs in the spanning tree can

be uniquely determined (*tree arcs*). It can be shown that the minimum cost flow problem has an optimal spanning-tree solution, and this optimal solution can be determined by moving from one feasible spanning-tree solution to the next by introducing one new non-tree arc into the spanning tree in the place of one tree arc. The successive spanning trees correspond to the basic feasible (or extreme point) solutions of linear programming, and moving from one spanning tree to the next is essentially a pivot operation in the simplex algorithm.

A spanning-tree solution partitions the arc set A into three subsets: (i) the arcs in the spanning tree, say T ; (ii) the non-tree arcs whose flow is zero, say L ; and (iii) the non-tree arcs whose flow is at the upper bound, say U . We refer to (T, L, U) as the *spanning-tree structure*. Given a

spanning-tree structure, we can determine the corresponding spanning-tree solution as follows. Set the flows on all arcs $(i, j) \in L$ to zero, the flow on all arcs $(i, j) \in U$ to u_{ij} , and then use the flow balance equations to determine the flow on all arcs in T . A spanning-tree structure is feasible if the corresponding spanning-tree solution satisfies all the arc flow bounds. If all the tree arcs in the spanning-tree solution are free arcs, then the solution is called *nondegenerate*; otherwise the solution is *degenerate*. The following theorem states a sufficient condition for a spanning-tree structure to be optimal. This theorem is analogous to the complementary slackness optimality conditions of linear programming.

A spanning-tree structure (T, L, U) is an optimal spanning-tree structure of the minimum cost flow problem if it is feasible and for some choice of node potentials π , the arc reduced costs $c_{ij}(\pi)$ satisfy the following conditions: (a) $c_{ij}(\pi) = 0$, for all $(i, j) \in T$; (b) $c_{ij}(\pi) \geq 0$, for all $(i, j) \in L$; and (c) $c_{ij}(\pi) \leq 0$ for all $(i, j) \in U$.

The network simplex algorithm maintains a feasible spanning-tree structure and moves from one spanning-tree structure to the next

until it finds the optimal spanning-tree structure. In each step, the algorithm adds one non-tree arc violating its optimality condition to the spanning tree in place of one of its current tree arcs. A non-tree arc violates its optimality condition if (i) its flow is at the lower bound and the reduced cost is negative; or (ii) its flow is at the upper bound and the reduced cost is positive. The algorithm (i) adds the arc to the spanning tree, creating a negative cycle; (ii) sends the maximum possible flow in this cycle until the flow on at least one arc in the cycle reaches its lower or upper bound; and (iii) drops an arc whose flow has reached its lower or upper bound from the tree, giving us a new spanning-tree structure. This operation of moving from one spanning-tree structure to another is known as a *pivot operation*, and the two spanning-tree structures obtained in consecutive iterations are called *adjacent spanning-tree structures*. The algorithm terminates when all non-tree arcs satisfy the optimality condition (the optimality of tree arcs is maintained throughout the algorithm). The algorithm is formally defined below.

algorithm *network simplex*;

begin

 determine an initial feasible tree structure (T, L, U) ;

 let x be the flow and π the node potentials associated with this tree structure;

while some non-tree arc violates the optimality conditions **do**

begin

 select an entering non-tree arc (k, l) violating its optimality condition;

 add arc (k, l) to the tree and determine the leaving arc (p, q) ;

 perform a tree update and update the solutions x and π ;

end;

end

We now describe the computation of node potentials π for a given spanning-tree structure (T, L, U) . Since the addition of a constant to all node potentials does not alter the reduced cost of any arc ($c_{ij}(\pi) = c_{ij} + \pi(i) - \pi(j)$), we assume without loss of generality that $\pi(1) = 0$. During each iteration of the algorithm, we compute node potentials that preserve the optimality condition for all tree arcs, $c_{ij}(\pi) = c_{ij} + \pi(i) - \pi(j) = 0$ for all $(i, j) \in T$. In order to achieve this, we start from node 1 and fan out such that whenever we

encounter a node k , we have already determined the potential of its predecessor. Arc flows are computed starting from a leaf node of the spanning-tree structure and moving toward the root while computing flows on arcs on the way.

In Fig. 7, we give an example for the network simplex algorithm. The non-tree arcs are dotted and the tree arcs are regular. We start with the initial solution shown in Fig. 7(a) and determine the node potentials and reduced costs. Non-tree arc $(1, 3)$ has flow

Figure 7. Illustration of the network simplex algorithm: (a) initial spanning-tree solution with $z = 18$; (b) spanning-tree solution with $z = 14$ obtained after (1,3) enters and (2,4) leaves; and (c) optimal spanning-tree solution with $z = 14$ obtained after (2,3) enters and (1,3) leaves.

at its lower bound and a negative reduced cost; we choose it as the entering arc. When (1, 3) enters, it creates a unique cycle 1-3-4-2-1; (1, 3) enters the tree and (2, 4) leaves the tree. The new solution and spanning-tree structure are shown in Fig. 7(b). We again compute the node potentials and reduced costs. Non-tree arc (2, 3) has flow at its upper bound and a positive reduced cost; we choose it as the entering arc. When (2, 3) enters, it creates the unique cycle 1-3-2-1; (2, 3) enters the tree and (1, 3) leaves the tree. The new solution and spanning-tree structure are shown in Fig. 7(c). We once again compute the node potentials and the reduced costs. Both non-tree arcs (1, 3) and

(2, 4) satisfy the optimality conditions and the algorithm terminates.

The network simplex algorithm moves from one spanning-tree structure to the next until it obtains a solution that satisfies the optimality conditions. If each pivot operation is nondegenerate, then since any network has a finite number of spanning-tree structures and every spanning-tree structure has a unique associated cost, the network simplex algorithm will encounter any spanning-tree structure at most once and will terminate finitely. However, degenerate pivots pose a difficulty due to *cycling*; that is, the algorithm goes through an infinite repetitive sequence of degenerate pivots. Computational studies

have shown that as many as 90% of the pivot operations in commonly encountered networks can be degenerate. Fortunately, it can be shown that by maintaining a special type of spanning tree called a *strongly feasible spanning tree*, the network simplex algorithm terminates finitely; moreover, it runs faster in practice as well.

INTRODUCTION

A prediction is a statement that a particular event will occur in the future, which can refer to the estimation of unknown situations in time series, cross-sectional, or longitudinal data. Prediction implies at least two factors: importance and difficulty [1]. Risk and uncertainty are crucial to prediction; thus it is important to minimize the prediction errors. There are no specifically assumed statistical distributions in the prediction models in this article.

In the first part of this article, we discuss two prediction models: the least square estimation (LSE) estimation model (section titled “LSE Model”), and the minimum mean square error (MMSE) model (section titled “MMSE Model Prediction”). Both of these two models aim at minimizing the square errors in their respective senses: (i) sum of squares, and (ii) mean square. LSE is known as a *linear deterministic model* that can be used to obtain approximate solutions of overdetermined systems. The application in the section titled “LSE Model” is to predict a limited-length time series $\{Z(i)\}$ from another limited-length time series $\{X(i)\}$, which can

be generalized to infinite-length time series case. In the section titled “Basic LSE Model”, by minimizing the sum of error squares in time series prediction, the *principle of orthogonality* is obtained as a necessary condition of reaching the global minimum error. It is further shown that the energy of the observed time series $\{Z(i)\}$ is the summation of the energy of the LSE estimation time series $\{Z_{\text{LSE estimation}}(i)\}$ and the energy of the LSE process time series $\{e(t)\}$. In the section titled “Another Approach to Understanding the LSE Model”, another way of understanding the LSE model is exhibited: a linear projection onto the column space of the data matrix $\mathbf{A}$, where the columns of $\mathbf{A}$ are composed of the time-delay vectors of the time series $\{X(i)\}$. In the section titled “MMSE Model Prediction”, we switch to a stochastic model: MMSE, which is also linear, to minimize the mean square error in prediction. We further show that the MMSE model is a special case of autoregressive moving average (ARMA)/(autoregressive integrated moving average) (ARIMA) models.

In the second part of this article (section titled “Causal Relations between Two, Three, and Multiple Variables in Prediction”), the causal relations in two or multiple time series are discussed in comparison, in statistical senses. In the section titled “Two-Variable (Time Series) Models” [2], we discuss (i) the simple causal model and (ii) the instantaneous causal model, between two time series $\{X_t\}$ and $\{Y_t\}$. We assume that the time series are wide-sense stationary and purely nondeterministic. In the simple causal model, the previous states of $\{X_t\}$ and $\{Y_t\}$ are used, to predict the present states of $\{X_t\}$ and $\{Y_t\}$, respectively. In the instantaneous causal model, the previous states of $\{X_t\}$, as well as the previous and present states of $\{Y_t\}$, are used to predict the present state of $\{X_t\}$; and vice versa. Though this is in stochastic sense, the *principle of orthogonality* (discussed in the section titled “LSE Model”) is still kept for minimizing prediction error. In the section titled “Three-Variable

(Time Series) Models” [2], the three-variable models are discussed briefly in frequency formulation. In the section titled “Multiple-Variable Models” [3], causal relations between one group of time series and the other group of time series are studied in frequency domain. The underlying *principle of orthogonality* is kept for error minimization.

Finally, we briefly discuss other prediction methods, that is, the Box–Jenkins Prediction.

LSE MODEL

Basic LSE Model

At the beginning of this article, the LSE model is presented.

In a causal system, consider two time series $X(i)$ and $Z(i)$ ($i = 0, 1, 2, 3, \dots$), where $X(i), X(i-1), X(i-2), \dots, X(i-M+1)$ are the unobserved underlying variables and influence the observed time series $Z(i)$ in a linear way, expressed as following

$$Z(i) = \sum_{k=0}^{M-1} w'_k X(i-k) + e'(i), \quad (1)$$

where w'_k ($k = 0, 1, 2, \dots, M-1$) are parameters of the LSE model and $e'(i)$ is the model error. The measurement error $e'(i)$ is unobservable and is used to count the model's inaccuracy.

Let

$$Y(i) \triangleq \sum_{k=0}^{M-1} w'_k X(i-k), \quad (2)$$

$$e'(i) \triangleq Z(i) - Y(i). \quad (3)$$

The measurement error process $e'(i)$ in the LSE model is assumed white with zero expectation and the same variance:

$$E(e'(i)) = 0, \quad \text{for all } i, \quad (4)$$

and

$$E(e'(i)e'(k)) = \sigma^2 I(i-k), \quad (5)$$

where

$$I(i-k) = \begin{cases} 1 & \text{if } i-k \neq 0 \\ 0 & \text{if } i-k = 0. \end{cases}$$

In the LSE model, given the observed data, we select/design the tap weights w'_k ($k = 0, 1, 2, \dots, M-1$) to minimize the sum of error squares (viewed as error energy). The objective function is as following:

$$\Theta(w'_0, w'_1, \dots, w'_{M-1}) = \sum_{i=s}^t [e'(i)]^2, \quad (6)$$

where s and t ($s \leq t$) are the index limits at which the error minimization occurs. Once the tap weights w'_k ($k = 0, 1, 2, \dots, M-1$) are selected, they are fixed as parameters in the interval $s \leq i \leq t$. Without losing generality, suppose index range of the observed data is $[1, N]$, and set $s = M, t = N$. Then, we get the observed input data matrix [4,5]:

$$\begin{bmatrix} X(M) & X(M+1) & \dots & X(N) \\ X(M-1) & X(M) & & X(N-1) \\ \vdots & & \ddots & \vdots \\ X(1) & X(2) & \dots & X(N-M+1) \end{bmatrix},$$

where the arrays above, from the first column (M) to the last column (N), correspond to the unobserved input variable vectors. Hence, the cost function in Equation (6) becomes

$$\Theta(w'_0, w'_1, \dots, w'_{M-1}) = \sum_{i=M}^N [e'(i)]^2, \quad (7)$$

Assume that $\Theta(w'_0, w'_1, \dots, w'_{M-1})$ is differentiable, then the necessary condition for minimizing $\Theta(w'_0, w'_1, \dots, w'_{M-1})$ is

$$\nabla \Theta = [0, 0, \dots, 0]^T \quad (M \text{ dimensional}). \quad (8)$$

Applying Equation (7) to Equation (8), we get

$$\begin{aligned} & \left[-2 \sum_{i=M}^N X(i-0)e'_{\min}(i), \right. \\ & \quad -2 \sum_{i=M}^N X(i-1)e'_{\min}(i), \dots, \\ & \quad \left. -2 \sum_{i=M}^N X(i-(M-1))e'_{\min}(i) \right]^T \\ & = [0, 0, \dots, 0]^T \quad (M \text{ dimensional}). \end{aligned} \quad (9)$$

Therefore, a necessary condition for $\Theta(w'_0, w'_1, \dots, w'_{M-1})$ to reach its global minimum is:

$$\sum_{i=M}^N X(i-k)e'_{\min}(i) = 0, \quad k = 0, 1, \dots, M-1. \quad (10)$$

Let the tap weights $w'_0, w'_1, \dots, w'_{M-1}$ that are optimized to operate the LSE condition have the special values $w_0^{\min}, w_1^{\min}, \dots, w_{M-1}^{\min}$. Then, we define $Y^{\min}(i)$ as

$$Y^{\min}(i) \triangleq \sum_{k=0}^{M-1} w_k^{\min} X(i-k). \quad (11)$$

Multiplying both sides of Equation (10) by $w_k^{\min}$ and then adding the results over the value of index k in the range $0, 1, 2, \dots, (M-1)$, we get

$$\sum_{k=0}^{M-1} w_k^{\min} \sum_{i=M}^N X(i-k)e'_{\min}(i) = 0. \quad (12)$$

Interchanging the order of summation, we get

$$\sum_{i=M}^N \left[\sum_{k=0}^{M-1} w_k^{\min} X(i-k) \right] e'_{\min}(i) = 0. \quad (13)$$

Using Equation (11) to substitute the inside summation item in Equation (13), we get

$$\sum_{i=M}^N Y_i^{\min} e'_{\min}(i) = 0. \quad (14)$$

Equation (14) is a necessary condition for global minimization of $\Theta(w'_0, w'_1, \dots, w'_{M-1})$, which is called the *principle of orthogonality*. In Equation (14), $Y_i^{\min}$ (defined in Equation (11)) is considered the least square (LS) estimate of the desired (observed) response $Z(i)$. Hence, $Y_i^{\min}$ can be written as $\hat{Z}^{\min}(i|X_i, X_{i-1}, \dots, X_{i-M+1})$, then Equation (14) can be reformulated as

$$\sum_{i=M}^N \hat{Z}^{\min}(i|X_i, X_{i-1}, \dots, X_{i-M+1}) e'_{\min}(i) = 0. \quad (15)$$

Taking the time average of the left-hand side of Equation (15), we find that the cross-correlation of two time series, $\hat{Z}^{\min}(i|X_i, X_{i-1}, \dots, X_{i-M+1})$ and $e_{\min}^*(i)$ is 0. So, the LSE estimate of the observed response $Z(i)$ represented by $\hat{Z}^{\min}(i|X_i, X_{i-1}, \dots, X_{i-M+1})$, and the LSE model error process $e_{\min}^*(i)$ are orthogonal over time.

$$\begin{aligned} \underbrace{Z(i)}_{\text{observed response}} &= \underbrace{\hat{Z}^{\min}(i|X_i, X_{i-1}, \dots, X_{i-M+1})}_{\text{estimate of observed response}} \\ &+ \underbrace{e'_{\min}(i)}_{\text{LSE model estimation error}} \end{aligned} \quad (16)$$

If we define

$$\begin{aligned} E_z &= \sum_{i=M}^N |Z(i)|^2 \\ E_{\text{LSE est}} &= \sum_{i=M}^N |\hat{Z}^{\min}(i|X_i, X_{i-1}, \dots, X_{i-M+1})|^2 \\ E_{\text{LSE error}} &= \sum_{i=M}^N |e_{\min}^*(i)|^2 \end{aligned}$$

by using the *principle of orthogonality* (Eq. 15), we get

$$E_z = E_{\text{LSE estimation}} + E_{\text{LSE error}}. \quad (17)$$

Equation (17) shows that the energy of the observed time series $Z(i)$ is the summation of the energy of the LSE estimation time series, and the energy of the LSE process time series [24]. All the three items in Equation (17) are nonnegative.

Another Approach to Understanding the LSE Model

Since $Y_i^{\min}$ in Equation (11) is also written as $\hat{Z}^{\min}(i|X_i, X_{i-1}, \dots, X_{i-M+1})$ in Equation (16), according to Equations (11) and 16, we get

$$e_{\min}^*(i) = Z(i) - \sum_{k=0}^{M-1} w_k^{\min} X(i-k). \quad (18)$$

Substituting Equation (18) into Equation (14), we get

$$\sum_{i=M}^N X(i-k) \left[Z(i) - \sum_{h=0}^{M-1} w_h^{\min} X(i-h) \right] = 0, \quad k = 0, 1, 2, \dots, M-1. \quad (19)$$

$$\Phi \triangleq \begin{bmatrix} \Phi(0,0) & \Phi(1,0) & \dots & \Phi(M-1,0) \\ \Phi(0,1) & \Phi(1,1) & \dots & \Phi(M-1,1) \\ \vdots & \vdots & \ddots & \vdots \\ \Phi(0,M-1) & \Phi(1,M-1) & \dots & \Phi(M-1,M-1) \end{bmatrix}. \quad (24)$$

Let the vector β (M by 1) be

$$\beta \triangleq [\beta(0) \quad \beta(-1) \quad \dots \quad \beta(-M+1)]^T. \quad (25)$$

Let the vector $w^{\min}$ (M by 1) be

$$w^{\min} \triangleq [w_0^{\min} \quad w_1^{\min} \quad \dots \quad w_{M-1}^{\min}]^T. \quad (26)$$

Then, Equation (23) can be rewritten as

$$\beta = \Phi w^{\min}. \quad (27)$$

Assuming Φ is nonsingular, then

$$w^{\min} = \Phi^{-1} \beta. \quad (28)$$

Reorganizing we get

$$\begin{aligned} & \sum_{i=M}^N X(i-k)Z(i) \\ &= \sum_{h=0}^{M-1} \left[w_h^{\min} \sum_{i=M}^N X(i-k)X(i-h) \right], \\ & k = 0, 1, 2, \dots, M-1. \end{aligned} \quad (20)$$

Here we define

$$\beta(-k) \triangleq \sum_{i=M}^N X(i-k)Z(i), \quad 0 \leq k \leq M-1. \quad (21)$$

$$\begin{aligned} \phi(h, k) &\triangleq \sum_{i=M}^N X(i-k)X(i-h), \\ 0 \leq h \leq M-1, \quad 0 \leq k \leq M-1. \end{aligned} \quad (22)$$

Then Equation (20) can be rewritten as

$$\begin{aligned} \beta(-k) &= \sum_{h=0}^{M-1} [w_h^{\min} \phi(h, k)], \\ k &= 0, 1, 2, \dots, M-1. \end{aligned} \quad (23)$$

Let the M by M matrix Φ be

Equation (28) is the design of a linear LSE estimation, where Φ^{-1} is the inverse of the time-average cross-correlation matrix and β is the cross-correlation vector between unobserved time series $\mathbf{X}$ and observed time series $\mathbf{Z}$. When noise is assumed to be white Gaussian distributed, its counterpart filter design is the Wiener-Hopf Equation.

According to Equations (22) and (24), Φ can be decomposed into

$$\Phi \triangleq \mathbf{A}^T \mathbf{A}, \quad (29)$$

where

$$\mathbf{A} \triangleq \begin{bmatrix} X(M) & X(M+1) & \cdots & X(N) \\ X(M-1) & X(M) & \cdots & X(N-1) \\ \vdots & \vdots & \ddots & \vdots \\ X(1) & X(2) & \cdots & X(N-M+1) \end{bmatrix}. \quad (30)$$

$$\text{Let } \mathbf{Z} \triangleq [Z(M) \ Z(M+1) \ \dots \ Z(N)]^T; \quad (31)$$

then, according to Equations (30) and (31) and the definition of β in Equations (21) and (25):

$$\beta \triangleq \mathbf{A}^T \mathbf{Z}. \quad (32)$$

Equation (27) can be rewritten as the following using the decomposition expression in Equation (29)

$$\beta = \mathbf{A}^T \mathbf{A} \mathbf{w}^{\min}. \quad (33)$$

Integrating Equations (32) and (33)

$$\mathbf{A}^T \mathbf{Z} = \mathbf{A}^T \mathbf{A} \mathbf{w}^{\min}. \quad (34)$$

Therefore,

$$\mathbf{w}^{\min} = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{Z}. \quad (35)$$

$$\text{Let } \mathbf{Y} = \hat{\mathbf{Z}}^{\min}$$

$$\triangleq [\hat{Z}^{\min}(M) \ \hat{Z}^{\min}(M+1) \ \dots \ \hat{Z}^{\min}(N)]^T, \quad (36)$$

Substituting Equation (35) into Equation (11), we get

$$\mathbf{Y} = \hat{\mathbf{Z}}^{\min} \triangleq \mathbf{A} \mathbf{w}^{\min} = \mathbf{A}(\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{Z}. \quad (37)$$

It is worth noting that $\mathbf{A}(\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T$ is the projection operator onto the linear space spanned by the columns of the data matrix $\mathbf{A}$.

Hence, the LSE estimation vector, which is expressed by $\hat{\mathbf{Z}}^{\min}$ or $\mathbf{Y}$, is the orthogonal projection of observable variable vector $\mathbf{Z}$ onto the linear space spanned by the columns of the data matrix $\mathbf{A}$. Suppose $M < N - M + 1$ (Fig. 1) [6]. If data matrix $\mathbf{A}$ is full rank, then its column space is an M -dimensional subspace of the $(N - M + 1)$ -dimensional full space. Assume that the data matrix $\mathbf{A}$ is already known with no uncertainty.

In practice, $\mathbf{A}$ could be unknown. In this case, a set of training data with limited length is used to estimate the LSE parameters. Some further properties of LSE are investigated by other literatures [7–10]. In an alternative way of thinking, $X(t)$ can be considered as another time series observed. Then, we interpret the problem as follows: the present states of time series $Z(t)$ can be predicted by the present and previous states of another time series $X(t)$, using the LSE model.

MMSE MODEL PREDICTION

Next, we introduce the MMSE prediction, described by the conditional expectation [11,12]:

$$\hat{X}_p(q) = E[X_{p+q} | X_p, X_{p-1}, \dots]. \quad (38)$$

Figure 1. The LSE prediction can be considered as the observed variable vector $\mathbf{Z}$ projected from the $(N - M + 1)$ -dimensional whole space onto the M -dimensional subspace spanned by columns of data matrix $\mathbf{A}$.

If we want a linear-form prediction, $\hat{X}_p(q)$ should have the following form [12,13]:

$$\hat{X}_p(q) = \sum_{i=0}^{p-1} w_i X_{p-i}. \quad (39)$$

Suppose we identify a particular model for a given time series, we need to estimate the model parameters and wish to compute forecasts from the fitted model (M_f) instead of the true model (M) (which we do not know). If we use a quadratic loss function, the best way to compute a forecast is to choose $\hat{X}_p(h)$ ($h = 1, 2, \dots, q-1$) to be the conditional expected value of $\hat{X}(p+h)$ on the model, and use information I_N available at time N .

$$\hat{X}_p(q) = E[X_{p+q} | M_f, I_N] \quad (40)$$

Then, the MMSE forecast with MA model of possibly infinite order would be [14]:

$$\hat{X}_p(q) = \sum_{i=q}^{\infty} w_i Z_{p+q-i}, \quad (41)$$

where the future values are replaced by zero.

More generally, the MMSE forecast from an ARMA model [15] can be computed by

$$\begin{aligned} \hat{X}_p(q) = & \sum_{i=1}^{q-1} \Theta_i \hat{X}_{p+q-i} \\ & + \sum_{i=q}^K \Theta_i X_{p+q-i} + \sum_{i=q}^J w_i Z_{p+q-i}, \end{aligned} \quad (42)$$

where the future value of Z is replaced by zero and the future values of X is replaced by the conditional expectation $\hat{X}$ [14].

Similarly, if we use the ARIMA model [15], then the MMSE forecast would be

$$\begin{aligned} & \hat{X}_p(q) - \hat{X}_p(q-1) \\ &= \sum_{i=1}^{q-2} \Theta_i (\hat{X}_{p+q-i} - \hat{X}_{p+q-1-i}) \\ &+ \Theta_{q-1} (\hat{X}_{p+1} - X_p) \\ &+ \sum_{i=q}^K \Theta_i (X_{p+q-i} - X_{p+q-1-i}) \\ &+ \sum_{t=q}^J w_t Z_{p+q-t}, \end{aligned} \quad (43)$$

where the future value of Z is replaced by zero and the future values of X are replaced by the conditional expectation of $\hat{X}$.

ARMA and ARIMA models can convert to each other, although generally ARMA models are used for accumulative value forecast, while ARIMA models are used for differential value forecast. For special cases, for example, ARIMA (0, 1, 1), it is a simple exponential smoothing. Recursive calculation is commonly used for the q -step MMSE forecast at time p using ARMA or ARIMA models.

CAUSAL RELATIONS BETWEEN TWO, THREE AND MULTIPLE VARIABLES IN PREDICTION

For time series prediction, in the section titled “LSE Model”, we discuss a deterministic model: LSE; in the section titled “MMSE Model Prediction”, we discuss a stochastic model: MMSE. Both the LSE and MMSE models aim at minimizing the prediction errors, in their respective senses. In this section, we continue to discuss on a wide-sense stationary, purely nondeterministic time series, for a closely related issue: the causal relations between multiple time series. We start from two-variable (time series) and three-variable (time series) models.

Two-Variable (Time Series) Models

Let X_t and Y_t be two wide-sense stationary, purely nondeterministic time series with zero

means. The *simple causal model* [2] is

$$X_t = \sum_{j=1}^m a_j X_{t-j} + \sum_{j=1}^m b_j Y_{t-j} + \varepsilon_t, \quad (44)$$

$$Y_t = \sum_{j=1}^m c_j X_{t-j} + \sum_{j=1}^m d_j Y_{t-j} + \eta_t, \quad (45)$$

where ε_t and η_t are the two zero-mean serially uncorrelated noise processes (time series) with $E(\varepsilon_t, \eta_s) = 0$ for any t and s . Since ε_t is serially uncorrelated, for any $p \neq q$, $E(\varepsilon_p, \varepsilon_q) = 0$. Since η_t is serially uncorrelated, for any $p \neq q$, $E(\eta_p, \eta_q) = 0$.

In the *simple causal model*, the previous states of $\{X_t\}$ and $\{Y_t\}$ are used to predict the present states of $\{X_t\}$ and $\{Y_t\}$, respectively.

A more general model—*instantaneous causal model* [2]—is

$$X_t = \sum_{j=1}^m a_j X_{t-j} + \sum_{j=0}^m b_j Y_{t-j} + \varepsilon_t, \quad (46)$$

$$Y_t = \sum_{j=0}^m c_j X_{t-j} + \sum_{j=1}^m d_j Y_{t-j} + \eta_t. \quad (47)$$

In the *instantaneous causal model*, the previous states of $\{X_t\}$, as well as the previous and present states of $\{Y_t\}$, are used to predict the present state of $\{X_t\}$. Similarly, the previous states of $\{Y_t\}$, as well as the previous and present states of $\{X_t\}$, are used to predict the present state of $\{Y_t\}$.

Comparing Equations (44) and (46), if the instantaneous causality is occurring ($b_0 \neq 0$), then the knowledge of the present state of $\{Y_t\}$ will improve the prediction for the present state of $\{X_t\}$, and $\text{var}(\varepsilon_t)$ will decrease. Similarly, comparing 45 and 47, if the instantaneous causality is occurring ($c_0 \neq 0$), then the knowledge of the present state of $\{X_t\}$ will improve the prediction for the present state of $\{Y_t\}$, and $\text{var}(\eta_t)$ will decrease.

To obtain the frequency formulation of the *simple causal model*, we can rewrite Equations (44) and (45) by using the time shift (delay) operator U , where $UX_t = X_{t-1}$

$$X_t = a(U)X_t + b(U)Y_t + \varepsilon_t, \quad (48)$$

$$Y_t = c(U)X_t + d(U)Y_t + \eta_t, \quad (49)$$

where $COEF(U)$ ($COEF = a, b, c, d$) are power series in U with the coefficient of U^0 being zero.

Next, we use *Cramer representation* of the series to get [2]:

$$X_t = \int_{-\pi}^{\pi} e^{it\omega} dZ_x(\omega), \quad (50)$$

$$Y_t = \int_{-\pi}^{\pi} e^{it\omega} dZ_y(\omega). \quad (51)$$

(*Cramer representation* is widely used in spectrum estimation for wide-sense stationary process; similar to the role of *Fourier transform* in time-frequency analysis in deterministic time series.)

Because k units of time shift (delay) (represented by U^k) in the *time domain* are equivalent to being multiplied by $e^{-i\omega k}$ in the *frequency domain*, and also noting that *Cramer representation* is a linear transformation, we get:

$$a(U)X_t = \int_{-\pi}^{\pi} e^{it\omega} a(e^{-i\omega}) dZ_x(\omega), \quad (52)$$

$$b(U)Y_t = \int_{-\pi}^{\pi} e^{it\omega} b(e^{-i\omega}) dZ_y(\omega), \quad (53)$$

$$c(U)X_t = \int_{-\pi}^{\pi} e^{it\omega} c(e^{-i\omega}) dZ_x(\omega), \quad (54)$$

$$d(U)Y_t = \int_{-\pi}^{\pi} e^{it\omega} d(e^{-i\omega}) dZ_y(\omega). \quad (55)$$

Integrating Equations (50)–(55) into Equations (48) and (49), we get (for every t)

$$\int_{-\pi}^{\pi} e^{it\omega} [(1 - a(e^{-i\omega})) dZ_x(\omega) - b(e^{-i\omega}) dZ_y(\omega) - dZ_\varepsilon(\omega)] = 0, \quad (56)$$

$$\int_{-\pi}^{\pi} e^{it\omega} [(-c(e^{-i\omega})) dZ_x(\omega) + (1 - d(e^{-i\omega})) dZ_y(\omega) - dZ_\eta(\omega)] = 0. \quad (57)$$

Because Equations (56) and (57) hold for every t , it further implies that

$$A(\omega) \begin{bmatrix} dZ_x(\omega) \\ dZ_y(\omega) \end{bmatrix} = \begin{bmatrix} dZ_\varepsilon(\omega) \\ dZ_\eta(\omega) \end{bmatrix}, \quad (58)$$

where $A(\omega) \triangleq \begin{bmatrix} 1 - a(e^{-i\omega}) & -b(e^{-i\omega}) \\ -c(e^{-i\omega}) & 1 - d(e^{-i\omega}) \end{bmatrix}$
for every $\omega \in [-\pi, \pi]$. Therefore,

$$\begin{bmatrix} dZ_x(\omega) \\ dZ_y(\omega) \end{bmatrix} = A(\omega)^{-1} \begin{bmatrix} dZ_\varepsilon(\omega) \\ dZ_\eta(\omega) \end{bmatrix} \quad (59)$$

Then, we obtain the spectral and cross-spectral matrices:

$$\begin{aligned} & \begin{bmatrix} f_x(\omega) & Cr(\omega) \\ Cr^*(\omega) & f_y(\omega) \end{bmatrix} \\ & \triangleq E \begin{bmatrix} dZ_x(\omega) \\ dZ_y(\omega) \end{bmatrix} \begin{bmatrix} \overline{dZ_x(\omega)} & \overline{dZ_y(\omega)} \end{bmatrix} \\ & = A(\omega)^{-1} E \left(\begin{bmatrix} dZ_\varepsilon(\omega) \\ dZ_\eta(\omega) \end{bmatrix} \begin{bmatrix} \overline{dZ_\varepsilon(\omega)} & \overline{dZ_\eta(\omega)} \end{bmatrix} \right) \\ & \quad \times (A(\omega)^*)^{-1} \\ & = A(\omega)^{-1} \begin{bmatrix} \sigma_\varepsilon(\omega)^2 & 0 \\ 0 & \sigma_\eta(\omega)^2 \end{bmatrix} (A(\omega)^T)^{-1}, \end{aligned} \quad (60)$$

where

$$\begin{aligned} f_x(\omega) &= \frac{1}{\Delta(\omega)} (|1 - d(e^{-i\omega})|^2 \sigma_\varepsilon(\omega)^2 \\ & \quad + |b(e^{-i\omega})|^2 \sigma_\eta(\omega)^2), \\ f_y(\omega) &= \frac{1}{\Delta(\omega)} (|c(e^{-i\omega})|^2 \sigma_\varepsilon(\omega)^2 \\ & \quad + |1 - a(e^{-i\omega})|^2 \sigma_\eta(\omega)^2, Cr(\omega) \\ & \triangleq C_1(\omega) + C_2(\omega) \\ & = \frac{1}{\Delta(\omega)} (1 - d(e^{-i\omega})) \overline{c(e^{-i\omega})} \sigma_\varepsilon(\omega)^2 \\ & \quad + \frac{1}{\Delta(\omega)} (1 - \overline{a(e^{-i\omega})}) b(e^{-i\omega}) \sigma_\eta(\omega)^2, \\ \Delta(\omega) &= |(1 - a(e^{-i\omega})) (1 - d(e^{-i\omega})) \\ & \quad - b(e^{-i\omega}) c(e^{-i\omega})|^2. \end{aligned}$$

When we study the causality between the two time series $\{X_t\}$ and $\{Y_t\}$, if $\{Y_t\}$ is NOT causing $\{X_t\}$, then $b(U) = 0$, $b(e^{-i\omega}) = 0$ for all ω , thus $C_2(\omega) = 0$; similarly, if $\{X_t\}$ is NOT causing $\{Y_t\}$, then $c(U) = 0$, $c(e^{-i\omega}) = 0$ for all ω , thus $C_1(\omega) = 0$. Therefore, the cross spectrum $Cr(\omega)$ can be decomposed into $C_1(\omega)$ and $C_2(\omega)$, representing “ $\{X_t\}$ causing $\{Y_t\}$ ” and “ $\{Y_t\}$ causing $\{X_t\}$ ”, respectively, that is,

$C_1(\omega)$ and $C_2(\omega)$ can be considered as two arms of the feedback mechanism.

In Equations (61) and (62), we define two measures of *strength of causality*: representing “ $\{X_t\}$ to $\{Y_t\}$ ” and “ $\{Y_t\}$ to $\{X_t\}$,” respectively:

$$\begin{aligned} C_{\mathbf{xy}}(\omega) &\triangleq \frac{|C_1(\omega)|^2}{f_x(\omega)f_y(\omega)} \\ &= \frac{|1 - d(e^{-i\omega})|^2 |c(e^{-i\omega})|^2 \sigma_\varepsilon(\omega)^2}{(|1 - d(e^{-i\omega})|^2 \sigma_\varepsilon(\omega)^2 \\ & \quad + |b(e^{-i\omega})|^2 \sigma_\eta(\omega)^2) (|c(e^{-i\omega})|^2 \sigma_\varepsilon(\omega)^2 + \\ & \quad |1 - a(e^{-i\omega})|^2 \sigma_\eta(\omega)^2)} \end{aligned} \quad (61)$$

$$\begin{aligned} C_{\mathbf{yx}}(\omega) &\triangleq \frac{|C_2(\omega)|^2}{f_x(\omega)f_y(\omega)} \\ &= \frac{|1 - a(e^{-i\omega})|^2 |b(e^{-i\omega})|^2 \sigma_\eta(\omega)^2}{(|1 - d(e^{-i\omega})|^2 \sigma_\varepsilon(\omega)^2 \\ & \quad + |b(e^{-i\omega})|^2 \sigma_\eta(\omega)^2) (|c(e^{-i\omega})|^2 \sigma_\varepsilon(\omega)^2 \\ & \quad + |1 - a(e^{-i\omega})|^2 \sigma_\eta(\omega)^2)} \end{aligned} \quad (62)$$

In Equations (63) and (64), the *causal phase* diagrams are further defined, to study the phase lag against frequency cross spectrum:

$$\phi_{\mathbf{xy}}(\omega) \triangleq \text{phase of } C_1(\omega), \quad (63)$$

$$\phi_{\mathbf{yx}}(\omega) \triangleq \text{phase of } C_2(\omega). \quad (64)$$

Similar to the frequency formulation of the *simple causal model* (Eqs 44 and 45), we consider the frequency formulation of the *instantaneous causal model* (Eqs 46 and 47). *Spectral and cross-spectral matrices* can be obtained similar to what is given by Equation (60) as follow:

$$\begin{aligned} & \begin{bmatrix} f_x(\omega) & Cr(\omega) \\ Cr^*(\omega) & f_y(\omega) \end{bmatrix} \\ & \triangleq E \begin{bmatrix} dZ_x(\omega) \\ dZ_y(\omega) \end{bmatrix} \begin{bmatrix} \overline{dZ_x(\omega)} & \overline{dZ_y(\omega)} \end{bmatrix} \\ & = A(\omega)^{-1} E \end{aligned}$$

$$\begin{aligned} & \times \left(\begin{bmatrix} dZ_\varepsilon(\omega) \\ dZ_\eta(\omega) \end{bmatrix} \begin{bmatrix} \overline{dZ_\varepsilon(\omega)} & \overline{dZ_\eta(\omega)} \end{bmatrix} \right) \\ & \times (A(\omega)^{*T})^{-1} = A(\omega)^{-1} \begin{bmatrix} \sigma_\varepsilon(\omega)^2 & 0 \\ 0 & \sigma_\eta(\omega)^2 \end{bmatrix} \\ & \times (A(\omega)^T)^{-1}, \end{aligned} \quad (65)$$

where

$$\begin{aligned} f_x(\omega) &= \frac{1}{\Delta(\omega)} (|1 - d(e^{-i\omega})|^2 \sigma_\varepsilon(\omega)^2 \\ & \quad + |b(e^{-i\omega})|^2 \sigma_\eta(\omega)^2) \\ f_y(\omega) &= \frac{1}{\Delta(\omega)} (|c(e^{-i\omega})|^2 \sigma_\varepsilon(\omega)^2 \\ & \quad + |1 - a(e^{-i\omega})|^2 \sigma_\eta(\omega)^2), Cr(\omega) \\ & \triangleq C_1(\omega) + C_2(\omega) \\ &= \frac{1}{\Delta(\omega)} (1 - d(e^{-i\omega})) \overline{(c(e^{-i\omega}) - c_0)} \sigma_\varepsilon(\omega)^2 \\ & \quad + \frac{1}{\Delta(\omega)} (1 - \overline{a(e^{-i\omega})}) (b(e^{-i\omega}) \\ & \quad - b_0) \sigma_\eta(\omega)^2, \\ \Delta(\omega) &= |(1 - a(e^{-i\omega}))(1 - d(e^{-i\omega})) \\ & \quad - (b(e^{-i\omega}) - b_0)(c(e^{-i\omega}) - c_0)|^2 \end{aligned}$$

(Note: b_0 and c_0 are the coefficients of instant causality of $\{Y_t\}$ in Equation (46) and $\{X_t\}$ in Equation (47), respectively)

Summary: the spectral methods can be applied to the analysis of causal relations between two time series $\{X_t\}$ and $\{Y_t\}$. Furthermore, the spectral methods in the frequency domain are robust in their interpretation, compared with the equation models in the time domain.

Three-Variable (Time Series) Models

Extending the two-variable model (*simple causal model*) in Equations (48) and (49) to

three-variable model [2], we get

$$X_t = a_1(U)X_t + b_1(U)Y_t + c_1(U)Z_t + \varepsilon_{1,t}, \quad (66)$$

$$Y_t = a_2(U)X_t + b_2(U)Y_t + c_2(U)Z_t + \varepsilon_{2,t}, \quad (67)$$

$$Z_t = a_3(U)X_t + b_3(U)Y_t + c_3(U)Z_t + \varepsilon_{3,t}. \quad (68)$$

Here we keep using the time shift operator U ($UX_t = X_{t-1}$). Since there is no instantaneous causality, the coefficients of U^0 are always zero.

Applying the frequency formulation (using *Cramer representation*) to the three-variable model, the spectral and cross-spectral matrices are obtained:

$$\begin{aligned} & \begin{bmatrix} f_x(\omega) & C_r^{xy}(\omega) & C_r^{xz}(\omega) \\ C_r^{xy*}(\omega) & f_y(\omega) & C_r^{yz}(\omega) \\ C_r^{xz*}(\omega) & C_r^{yz*}(\omega) & f_z(\omega) \end{bmatrix} \\ &= E \begin{bmatrix} dZ_x(\omega) \\ dZ_y(\omega) \\ dZ_z(\omega) \end{bmatrix} \\ & \quad \times \begin{bmatrix} \overline{dZ_x(\omega)} & \overline{dZ_y(\omega)} & \overline{dZ_z(\omega)} \end{bmatrix} \\ &= A(\omega)^{-1} E \begin{bmatrix} dZ_{\varepsilon 1}(\omega) \\ dZ_{\varepsilon 2}(\omega) \\ dZ_{\varepsilon 3}(\omega) \end{bmatrix} \\ & \quad \times \begin{bmatrix} \overline{dZ_{\varepsilon 1}(\omega)} & \overline{dZ_{\varepsilon 2}(\omega)} & \overline{dZ_{\varepsilon 3}(\omega)} \end{bmatrix} \\ & \quad \times (A(\omega)^{*T})^{-1} \\ &= A(\omega)^{-1} \begin{bmatrix} \sigma_1(\omega)^2 & 0 & 0 \\ 0 & \sigma_2(\omega)^2 & 0 \\ 0 & 0 & \sigma_3(\omega)^2 \end{bmatrix} \\ & \quad \times (A(\omega)^{*T})^{-1}, \end{aligned} \quad (69)$$

where

$$A = \begin{bmatrix} 1 - a_1(e^{-i\omega}) & -b_1(e^{-i\omega}) & -c_1(e^{-i\omega}) \\ -a_2(e^{-i\omega}) & 1 - b_2(e^{-i\omega}) & -c_2(e^{-i\omega}) \\ -a_3(e^{-i\omega}) & -b_3(e^{-i\omega}) & 1 - c_3(e^{-i\omega}) \end{bmatrix}$$

Similar to the calculation in the two-variable model, the power spectrum of X_t ,

Y_t , and Z_t , as well as the cross spectrum: $C_r^{xy}(\omega)$, $C_r^{xz}(\omega)$, and $C_r^{yz}(\omega)$, can be calculated in the three-variable model.

Further, the *Partial cross spectrum* between X_t and Y_t given Z_t is defined as $C_r^{xy,z}(\omega) \triangleq C_r^{xy}(\omega) - C_r^{xz}(\omega)f_z(\omega)^{-1}C_r^{zy}(\omega)$, where $C_r^{xy}(\omega)$, $C_r^{xz}(\omega)$, $C_r^{zy}(\omega)$, $f_z(\omega)$ are derived from Equation (69). When *partial cross spectrum* is considered, more useful results arise.

$$\begin{aligned} C_r^{xy,z}(\omega) &= \frac{1}{\Delta_Z(\omega)} \sigma_1^2 \sigma_2^2 b_3(e^{-i\omega}) a_3(e^{-i\omega}) \\ &\quad - \frac{1}{\Delta_Z(\omega)} \sigma_1^2 \sigma_2^2 (b_2(e^{-i\omega}) - 1) a_2(e^{-i\omega}) \\ &\quad - \frac{1}{\Delta_Z(\omega)} \sigma_2^2 \sigma_3^2 b_1(e^{-i\omega}) (a_1(e^{-i\omega}) - 1) \\ &\triangleq C_{r1}^{xy,z}(\omega) + C_{r2}^{xy,z}(\omega) + C_{r3}^{xy,z}(\omega), \end{aligned} \quad (70)$$

where

$$\begin{aligned} \Delta_Z(\omega) &= \sigma_1^2 |(b_2(e^{-i\omega}) - 1)(c_3(e^{-i\omega}) - 1) \\ &\quad - c_2(e^{-i\omega})b_3(e^{-i\omega})|^2 \\ &\quad + \sigma_2^2 |c_1(e^{-i\omega})b_3(e^{-i\omega}) \\ &\quad - b_1(e^{-i\omega})(c_3(e^{-i\omega}) - 1)|^2 \\ &\quad + \sigma_3^2 |b_1(e^{-i\omega})c_2(e^{-i\omega}) \\ &\quad - c_1(e^{-i\omega})(b_2(e^{-i\omega}) - 1)|^2. \end{aligned}$$

As shown in Equation (70), the partial cross spectrum between X_t and Y_t can be decomposed into $C_{r1}^{xy,z}(\omega)$, $C_{r2}^{xy,z}(\omega)$, and $C_{r3}^{xy,z}(\omega)$, where the first component represents the relation between X_t and Y_t through Z_t , and the second and third components together represent generalizations of the causal cross spectra (between X_t and Y_t), which come from the two-variable case.

Multiple-Variable Models

Generalizing the two- and three-variable causal relation models to multiple-variable models brings in-depth insights into the causal relation and feedback problem [3]. In this section, causal relations between one group of time series and another group of time series are studied. The discussion in this section is still based on wide-sense stationary, purely nondeterministic time series.

Let $\mathbf{V}_t : m$ by 1 be a zero-mean wide-sense stationary, purely nondeterministic

multiple time series. And suppose that $\mathbf{V}_t$ has been partitioned into two sub-vectors: $\mathbf{V}_t^T = [\mathbf{X}_t^T, \mathbf{Y}_t^T]$, $\mathbf{X}_t : k$ by 1 and $\mathbf{Y}_t : l$ by 1, $m = k + l$. We try to find out the causal relations as well as the measurement of linear dependence and feedback between $\mathbf{X}_t : k$ by 1 and $\mathbf{Y}_t : l$ by 1.

By assuming the existence of the spectral density matrix $S_{\mathbf{V}}(\omega)$ at all frequencies $\omega \in [-\pi, \pi]$, we have a corresponding partition of the spectral density matrix $S_{\mathbf{V}}(\omega)$:

$$S_{\mathbf{V}}(\omega) = \begin{bmatrix} S_{\mathbf{X}}(\omega) & S_{\mathbf{X}\mathbf{Y}}(\omega) \\ S_{\mathbf{Y}\mathbf{X}}(\omega) & S_{\mathbf{Y}}(\omega) \end{bmatrix}. \quad (71)$$

We assume that there is a moving average representation of $\mathbf{V}_t : m$ by 1 as follows:

$$\mathbf{V}_t = \sum_{r=0}^{\infty} \mathbf{A}_r \boldsymbol{\varepsilon}_{t-r}, \quad E(\boldsymbol{\varepsilon}_t) = 0, \text{var}(\boldsymbol{\varepsilon}_t) = \gamma, \quad (72)$$

where $\boldsymbol{\varepsilon}_{t-r}$ is serially uncorrelated; for any $\sum_{r=0}^{\infty} \mathbf{A}_r \mathbf{Z}^r = 0$, $|\mathbf{Z}| \geq 1$ holds; and $\sum_{r=0}^{\infty} \|\mathbf{A}_r\|^2 < \infty$. ($\|P\|$ is the square root of the largest eigenvalue of $P'P$; $|P|$ is the square root of the determinant of $P'P$). The existence of moving average representation is equivalent to the existence of the spectral density matrix $S_{\mathbf{V}}(\omega)$ at almost all frequencies $\omega \in [-\pi, \pi]$ [16]. Furthermore, a lower bound on the mean-squared error of one-step-ahead minimum mean γ is given by using $S_{\mathbf{V}}(\omega)$:

$$\ln |\gamma| = \frac{1}{2\pi} \int_{-\pi}^{\pi} \ln |S_{\mathbf{V}}(\omega)| d\omega. \quad (73)$$

If there exists a constant $\text{CONST} \geq 1$ such that for almost all $\omega \in [-\pi, \pi]$, [17]

$$\text{CONST}^{-1} I_n \leq S_{\mathbf{V}}(\omega) \leq \text{CONST} I_n. \quad (74)$$

(This means that both $(\text{CONST} I_n - S_{\mathbf{V}}(\omega))$ and $(S_{\mathbf{V}}(\omega) - \text{CONST}^{-1} I_n)$ are positive semidefinite, and that the spectral density matrix is bounded uniformly away from zero almost everywhere in $[-\pi, \pi]$, which is weaker than the condition that $\mathbf{V}_t$ is an ARMA process of finite orders with invertible AR and MA parts.)

Then, the relationship in Equation (70) can be inverted so that $\mathbf{V}_t$ become a function of $\{\mathbf{V}_{t-r}, r \geq 1\}$ and $\boldsymbol{\varepsilon}_t$.

$$\mathbf{V}_t = \sum_{r=1}^{\infty} B_r \mathbf{V}_{t-r} + \boldsymbol{\varepsilon}_t, \quad E(\boldsymbol{\varepsilon}_t) = 0, \text{var}(\boldsymbol{\varepsilon}_t) = \gamma. \quad (75)$$

Predict from its Own Past. Considering that $\mathbf{V}_t$ has been partitioned into two sub-vectors $\mathbf{V}_t^T = [\mathbf{X}_t^T, \mathbf{Y}_t^T]$, if the condition in Equation (73) holds, then each of $\mathbf{X}_t$ and $\mathbf{Y}_t$ has an autoregressive (AR) representation denoted by

$$\mathbf{X}_t = \sum_{r=1}^{\infty} \mathbf{E}1_r \mathbf{X}_{t-r} + \boldsymbol{\eta}1_t, \quad E(\boldsymbol{\eta}1_t) = 0, \text{var}(\boldsymbol{\eta}1_t) = \Gamma 1; \quad (76)$$

$$\mathbf{Y}_t = \sum_{r=1}^{\infty} \mathbf{G}1_r \mathbf{Y}_{t-r} + \boldsymbol{\sigma}1_t, \quad E(\boldsymbol{\sigma}1_t) = 0, \text{var}(\boldsymbol{\sigma}1_t) = \Xi 1; \quad (77)$$

where $\boldsymbol{\eta}1_t$ is one-step-ahead error when $\mathbf{X}_t$ is predicted from its own past $\{\mathbf{X}_{t-r}, r \geq 1\}$; similarly, $\boldsymbol{\sigma}1_t$ is one-step-ahead error when $\mathbf{Y}_t$ is predicted from its own past $\{\mathbf{Y}_{t-r}, r \geq 1\}$. Recall Equations (15), (16) and (17) (the *principle of orthogonality*) in the LSE model in the section titled “Basic LSE Model”. By generalizing the *principle of orthogonality* to infinite orders, to minimize the one-step prediction error, $\boldsymbol{\eta}1_t$ is orthogonal (uncorrelated) to $\sum_{r=1}^{\infty} \mathbf{E}1_r \mathbf{X}_{t-r}$ (the projection of $\mathbf{X}_t$ on its own past), and $\boldsymbol{\sigma}1_t$ is orthogonal (uncorrelated) to $\sum_{r=1}^{\infty} \mathbf{G}1_r \mathbf{Y}_{t-r}$ (the projection of $\mathbf{Y}_t$ on its own past). Thus, $\boldsymbol{\eta}1_t$ and $\boldsymbol{\sigma}1_t$ are by themselves serially uncorrelated. But $\boldsymbol{\eta}1_t$ and $\boldsymbol{\sigma}1_t$ may be correlated with each other contemporaneously and at various leads and lags.

Predict from Its Own Past and the Other’s Past. A further step to take is the projection of $\mathbf{X}_t$ on its own past and the past of $\mathbf{Y}_t$, and the projection of $\mathbf{Y}_t$ on its own past and the

past of $\mathbf{X}_t$, as follows:

$$\mathbf{X}_t = \sum_{r=1}^{\infty} \mathbf{E}2_r \mathbf{X}_{t-r} + \sum_{r=1}^{\infty} \mathbf{F}2_r \mathbf{Y}_{t-r} + \boldsymbol{\eta}2_t, \quad E(\boldsymbol{\eta}2_t) = 0, \text{var}(\boldsymbol{\eta}2_t) = \Gamma 2; \quad (78)$$

$$\mathbf{Y}_t = \sum_{r=1}^{\infty} \mathbf{H}2_r \mathbf{X}_{t-r} + \sum_{r=1}^{\infty} \mathbf{G}2_r \mathbf{Y}_{t-r} + \boldsymbol{\sigma}2_t, \quad E(\boldsymbol{\sigma}2_t) = 0, \text{var}(\boldsymbol{\sigma}2_t) = \Xi 2. \quad (79)$$

By generalizing the *principle of orthogonality* in the section titled “Basic LSE Model” (LSE model) to infinite orders, $\boldsymbol{\eta}2_t$ is orthogonal (uncorrelated) to $\sum_{r=1}^{\infty} \mathbf{E}2_r \mathbf{X}_{t-r} + \sum_{r=1}^{\infty} \mathbf{F}2_r \mathbf{Y}_{t-r}$ (the projection of $\mathbf{X}_t$ on $\{\mathbf{X}_{t-r}, r \geq 1\}$ and $\{\mathbf{Y}_{t-r}, r \geq 1\}$), and $\boldsymbol{\sigma}2_t$ is orthogonal (uncorrelated) to $\sum_{r=1}^{\infty} \mathbf{G}2_r \mathbf{Y}_{t-r} + \sum_{r=1}^{\infty} \mathbf{H}2_r \mathbf{X}_{t-r}$ (the projection of $\mathbf{Y}_t$ on $\{\mathbf{X}_{t-r}, r \geq 1\}$ and $\{\mathbf{Y}_{t-r}, r \geq 1\}$), to minimize the one-step prediction error. Thus, $\boldsymbol{\eta}2_t$ and $\boldsymbol{\sigma}2_t$ are by themselves serially uncorrelated. But $\boldsymbol{\eta}2_t$ and $\boldsymbol{\sigma}2_t$ may be correlated with each other contemporaneously and at various leads and lags.

The linear prediction model in Equations (77) and (78) is another expression of the linear prediction model in Equation (74). The two expressions are the same intrinsically, considering $\mathbf{V}_t^T = [\mathbf{X}_t^T, \mathbf{Y}_t^T]$.

Therefore, $\boldsymbol{\varepsilon}_t^T = [\boldsymbol{\eta}2_t^T, \boldsymbol{\sigma}2_t^T]$ and we have the partition of γ as follows:

$$\begin{aligned} \gamma &= \text{var}(\boldsymbol{\varepsilon}_t) \\ &= \text{var} \begin{pmatrix} \boldsymbol{\eta}2_t \\ \boldsymbol{\sigma}2_t \end{pmatrix} \\ &= \begin{bmatrix} \Gamma 2 & \text{Cov}_{xy} \\ \text{Cov}_{xy}' & \Xi 2 \end{bmatrix}. \end{aligned} \quad (80)$$

Predict from Its Own Past and the Other’s Present and Past. A third step to take is to pre-multiply the following matrix on Equations (77) and (78)

$$\begin{bmatrix} I_k & -\text{Cov}_{xy} \Xi 2^{-1} \\ -\text{Cov}_{xy}' \Gamma 2^{-1} & I_l \end{bmatrix}$$

Then, the first k equations can be considered as a new linear system of $\mathbf{X}_t$, projected on $\{\mathbf{X}_{t-r}, r \geq 1\}$ and $\{\mathbf{Y}_{t-r}, r \geq 0\}$;

similarly, the next l equations can be considered a new linear system of $\mathbf{Y}_t$, projected on $\{\mathbf{X}_{t-r}, r \geq 0\}$ and $\{\mathbf{Y}_{t-r}, r \geq 1\}$, as follow:

$$\mathbf{X}_t = \sum_{r=1}^{\infty} \mathbf{E}\mathbf{3}_r \mathbf{X}_{t-r} + \sum_{r=0}^{\infty} \mathbf{F}\mathbf{3}_r \mathbf{Y}_{t-r} + \eta\mathbf{3}_t,$$

$$E(\eta\mathbf{3}_t) = 0, \text{var}(\eta\mathbf{3}_t) = \mathbf{\Gamma}\mathbf{3}; \quad (81)$$

$$\mathbf{Y}_t = \sum_{r=0}^{\infty} \mathbf{H}\mathbf{3}_r \mathbf{X}_{t-r} + \sum_{r=1}^{\infty} \mathbf{G}\mathbf{3}_r \mathbf{Y}_{t-r} + \sigma\mathbf{3}_t,$$

$$E(\sigma\mathbf{3}_t) = 0, \text{var}(\sigma\mathbf{3}_t) = \mathbf{E}\mathbf{3}; \quad (82)$$

where

$$\eta\mathbf{3}_t = \eta\mathbf{2}_t - \text{Cov}_{xy} \mathbf{\Xi} \mathbf{2}^{-1} \sigma\mathbf{2}_t, \quad (83)$$

$$\sigma\mathbf{3}_t = \sigma\mathbf{2}_t - \text{Cov}'_{xy} \mathbf{\Gamma} \mathbf{2}^{-1} \eta\mathbf{2}_t. \quad (84)$$

(Hence, $E(\eta\mathbf{3}_t) = E(\eta\mathbf{2}_t) - \text{Cov}_{xy} \mathbf{\Xi} \mathbf{2}^{-1} E(\sigma\mathbf{2}_t) = 0 - \text{Cov}_{xy} \mathbf{\Xi} \mathbf{2}^{-1} \mathbf{0} = 0$, and similarly one can prove that $E(\sigma\mathbf{3}_t) = 0$.)

Note that each of $\eta\mathbf{2}_t$ and $\sigma\mathbf{2}_t$ is uncorrelated (orthogonal) to both $\{\mathbf{X}_{t-r}, r \geq 1\}$ and $\{\mathbf{Y}_{t-r}, r \geq 1\}$ as already discussed above. According to Equations (82) and (83), each of $\eta\mathbf{3}_t$ and $\sigma\mathbf{3}_t$ is uncorrelated to both $\{\mathbf{X}_{t-r}, r \geq 1\}$ and $\{\mathbf{Y}_{t-r}, r \geq 1\}$.

According to Equation (82), $\eta\mathbf{3}_t$ is also uncorrelated to $\sigma\mathbf{2}_t$: $\text{Cov}(\eta\mathbf{3}_t, \sigma\mathbf{2}_t) = E(\eta\mathbf{3}_t \sigma\mathbf{2}_t^T) = E((\eta\mathbf{2}_t - \text{Cov}_{xy} \mathbf{\Xi} \mathbf{2}^{-1} \sigma\mathbf{2}_t) \sigma\mathbf{2}_t^T) = \text{Cov}_{xy} - \text{Cov}_{xy} \mathbf{\Xi} \mathbf{2}^{-1} \mathbf{\Xi} \mathbf{2} = 0$.

Hence, $\eta\mathbf{3}_t$ is uncorrelated to all $\sigma\mathbf{2}_t$, $\{\mathbf{X}_{t-r}, r \geq 1\}$ and $\{\mathbf{Y}_{t-r}, r \geq 1\}$. According to Equation (78), $\eta\mathbf{3}_t$ is uncorrelated to $\mathbf{Y}_t$. Thus, $\eta\mathbf{3}_t$ is uncorrelated to $\{\mathbf{X}_{t-r}, r \geq 1\}$, and $\{\mathbf{Y}_{t-r}, r \geq 0\}$. Therefore, Equation (80) is a linear (orthogonal) projection of $\mathbf{X}_t$ on $\{\mathbf{X}_{t-r}, r \geq 1\}$ and $\{\mathbf{Y}_{t-r}, r \geq 0\}$. Similarly, according to Equation (83), $\sigma\mathbf{3}_t$ is also uncorrelated to $\eta\mathbf{2}_t$: $\text{Cov}(\sigma\mathbf{3}_t, \eta\mathbf{2}_t) = E(\sigma\mathbf{3}_t \eta\mathbf{2}_t^T) = E((\sigma\mathbf{2}_t - \text{Cov}'_{xy} \mathbf{\Gamma} \mathbf{2}^{-1} \eta\mathbf{2}_t) \eta\mathbf{2}_t^T) = \text{Cov}'_{xy} - \text{Cov}'_{xy} \mathbf{\Gamma} \mathbf{2}^{-1} \mathbf{\Gamma} \mathbf{2} = 0$.

Hence, $\sigma\mathbf{3}_t$ is uncorrelated to all $\eta\mathbf{2}_t$, $\{\mathbf{X}_{t-r}, r \geq 1\}$ and $\{\mathbf{Y}_{t-r}, r \geq 1\}$. According to Eq. 77, $\eta\mathbf{3}_t$ is uncorrelated to $\mathbf{X}_t$. Thus, $\sigma\mathbf{3}_t$ is uncorrelated to $\{\mathbf{X}_{t-r}, r \geq 0\}$, and $\{\mathbf{Y}_{t-r}, r \geq 1\}$. Therefore, Equation (81) is a linear (orthogonal) projection of $\mathbf{Y}_t$ on $\{\mathbf{X}_{t-r}, r \geq 0\}$ and $\{\mathbf{Y}_{t-r}, r \geq 1\}$.

Predict from Its Own Past and the Other's Temporally Complete Information.

A final step is to consider the linear projection of $\mathbf{X}_t$ on $\{\mathbf{X}_{t-r}, r \geq 1\}$ and $\{\mathbf{Y}_{t-r}, \text{integer } r \in (-\infty, \infty)\}$, and the linear projection of $\mathbf{Y}_t$ on $\{\mathbf{X}_{t-r}, \text{integer } r \in (-\infty, \infty)\}$ and $\{\mathbf{Y}_{t-r}, r \geq 1\}$.

Recall the partition of the spectral density matrix $\mathbf{S}_V(\omega)$ in Equation (70). Let

$$\tilde{L}(\omega) = \mathbf{S}_{\mathbf{X}\mathbf{Y}}(\omega) \mathbf{S}_{\mathbf{Y}}(\omega)^{-1} \quad \text{for all } \omega \in [-\pi, \pi] \quad (85)$$

(Assume that Equation (73) is true; then, the spectral density matrix exists and is bounded uniformly away from zero almost everywhere in $[-\pi, \pi]$) Use inverse Fourier transform of $\tilde{L}(\omega)$:

$$L_r = \frac{1}{2\pi} \int_{-\pi}^{\pi} \tilde{L}(\omega) e^{-i\omega r} d\omega. \quad (86)$$

Let

$$\mathbf{W}_t = \mathbf{X}_t - \sum_{r=-\infty}^{\infty} L_r \mathbf{Y}_{t-r}. \quad (87)$$

Then, from the spectral representation of $\mathbf{V}$ (Eq. 70), it is be proved that $\mathbf{W}_t$ is uncorrelated (orthogonal) with all $\{\mathbf{Y}_r, \text{integer } r \in (-\infty, \infty)\}$.

Therefore, if we rewrite Equation (86) in $\mathbf{X}_t = \sum_{r=-\infty}^{\infty} L_r \mathbf{Y}_{t-r} + \mathbf{W}_t$, then Equation (86) can be considered as an expression of the linear projection of $\mathbf{X}_t$ on $\{\mathbf{Y}_r, \text{integer } r \in (-\infty, \infty)\}$.

From Equations (70) and (86), it can be further shown that

$$\mathbf{S}_W(\omega) = \mathbf{S}_X(\omega) - \mathbf{S}_{\mathbf{X}\mathbf{Y}}(\omega) \mathbf{S}_{\mathbf{Y}}(\omega)^{-1} \mathbf{S}_{\mathbf{Y}\mathbf{X}}(\omega) \quad \text{for all } \omega \in [-\pi, \pi]. \quad (88)$$

Considering the assumption in Equation (73): because $\mathbf{S}_W(\omega)$ consists of the first k rows and columns of $\mathbf{S}_V(\omega)$, and Equation (73) holds, we also have

$$\text{CONST}^{-1} I_k \leq \mathbf{S}_W(\omega) \leq \text{CONST} I_k. \quad (89)$$

(For some constant CONST and for all $\omega \in [-\pi, \pi]$ in the above equation)

Therefore, $\mathbf{W}_t$ has an autoregressive representation, as follows:

$$\mathbf{W}_t = \sum_{r=1}^{\infty} D_r \mathbf{W}_{t-r} + \boldsymbol{\eta}_t, \\ E(\boldsymbol{\eta}_t) = 0, \text{var}(\boldsymbol{\eta}_t) = \boldsymbol{\Gamma} \mathbf{4}, \quad (90)$$

where $(\boldsymbol{\eta}_t)$ is uncorrelated (orthogonal) with $\{\mathbf{W}_{t-r}, r \geq 1\}$.

Using $\mathbf{X}_t = \sum_{r=-\infty}^{\infty} L_r \mathbf{Y}_{t-r} + \mathbf{W}_t$ from Equation (86) to substitute all $\{\mathbf{W}_{t-r}, r \geq 1\}$ in Equation (89), after reorganizing, we get

$$\mathbf{X}_t = \sum_{r=1}^{\infty} \mathbf{E} \mathbf{4}_r \mathbf{X}_{t-r} + \sum_{r=-\infty}^{\infty} \mathbf{F} \mathbf{4}_r \mathbf{Y}_{t-r} + \boldsymbol{\eta}_t, \\ E(\boldsymbol{\eta}_t) = 0, \text{var}(\boldsymbol{\eta}_t) = \boldsymbol{\Gamma} \mathbf{4}. \quad (91)$$

By Equation (89), $\boldsymbol{\eta}_t$ is a linear function of $\{\mathbf{W}_{t-r}, r \geq 1\}$, and since any $\{\mathbf{W}_r, \text{integer } r \in (-\infty, \infty)\}$ is uncorrelated (orthogonal) with all $\{\mathbf{Y}_r, \text{integer } r \in (-\infty, \infty)\}$, therefore, $\boldsymbol{\eta}_t$ is uncorrelated with all $\{\mathbf{Y}_r, \text{integer } r \in (-\infty, \infty)\}$.

According to Equation (86), $\mathbf{X}_s$ is a linear function of $\{\mathbf{Y}_r, \text{integer } r \in (-\infty, \infty)\}$ and $\mathbf{W}_s$ for any integer s . Also, $\boldsymbol{\eta}_t$ is uncorrelated (orthogonal) with $\{\mathbf{W}_{t-r}, r \geq 1\}$, as already discussed above. Therefore, $\boldsymbol{\eta}_t$ is uncorrelated with $\{\mathbf{X}_{t-r}, r \geq 1\}$.

Hence, Equation (90) is the linear projection of $\mathbf{X}_t$ on $\{\mathbf{X}_{t-r}, r \geq 1\}$ and $\{\mathbf{Y}_r, \text{integer } r \in (-\infty, \infty)\}$.

Similarly (symmetrically), Equation (91) is the linear projection of $\mathbf{Y}_t$ on $\{\mathbf{Y}_{t-r}, r \geq 1\}$ and $\{\mathbf{X}_r, \text{integer } r \in (-\infty, \infty)\}$.

$$\mathbf{Y}_t = \sum_{r=-\infty}^{\infty} \mathbf{H} \mathbf{4}_r \mathbf{X}_{t-r} + \sum_{r=1}^{\infty} \mathbf{G} \mathbf{4}_r \mathbf{Y}_{t-r} + \boldsymbol{\eta}_t, \\ E(\boldsymbol{\sigma}_t) = 0, \text{var}(\boldsymbol{\sigma}_t) = \boldsymbol{\Xi} \mathbf{4}. \quad (92)$$

It is worth mentioning that all the prediction models in the section titled “Causal Relations between Two, Three, and Multiple Variables in Prediction” are based on the assumption that the time series analyzed are a zero-mean wide-sense stationary, and purely nondeterministic. The analysis could be extended to some nonstationary and

purely nondeterministic time series, and similar autoregressive representations can be obtained.

OTHER PREDICTION METHODS

To handle nonstationarity and seasonality, the prediction process needs to select a suitable model for a given time series. The prediction based on the more general class of ARIMA or seasonal autoregressive integrated moving average (SARIMA) models is called the *Box–Jenkins prediction* [14]. The model involves an iterative procedure with: (i) formulating, (ii) fitting, (iii) checking and adjusting.

Depending on how the first few observations are treated, there exist different prediction procedures for fitting ARIMA models (e.g., maximum likelihood and conditional least square). But only for short series (not more than several hundred points), the choice of procedures is important and makes a significant difference. It is shown that for short series even when asymptotically unbiased, parameter estimates are likely to be biased [18]. Furthermore, different software packages, using different estimation routines, can produce model parameter estimates with nontrivial differences [19]. Hence, it is a wise choice to use the software which exactly specifies what estimation procedures are adopted.

The way that trend is removed before applying the Box–Jenkins approach can be vital for nonstationary time series. Especially, the order of differencing can be crucial if differencing is applied. Alternative methods of removing trend, prior to fitting an ARIMA model, may lead to better forecasting [20].

CONCLUDING REMARKS

In this article, we discuss the *rolling method*, which is a projection based on past performances, and which is periodically updated on a regular schedule to incorporate data (e.g., LSE). Especially, in the LSE model, the orthogonality principle is discussed, which

is widely used in different prediction models. There are also derivative models of LSE, which intrinsically keep the same orthogonality principle, that is, the total least squares (TLS), the robust least squares (RLS), and the ordinary least squares (OLS).

We also discuss the causal models, which are under the assumption that it is possible to identify the underlying factors that might influence the variable that is being predicted (e.g., ARMA; ARIMA; and Granger causality). The Granger causality basically is studying the causal relations between/among two or multiple time series, and is widely used in neuroscience, cognitive research, and economics. The predicting power of Granger causality models can be explored if all the time series can be considered as in one system. We further categorized and discussed Granger causality against two time series, three time series, and more generally, two groups of time series. In each of those cases, there are some results, which can benefit the prediction.

There are other categories of prediction methods that are not included here in this article, like the ensemble prediction, simulation methods, or the judgmental methods incorporating intuitive judgments, opinions, and subjective probability estimates (e.g., composite prediction; Delphi method; and scenario building) [21–23]. Different models have their respective limitations and advantages in difference scenarios.

Most of the well-known network-based combinatorial optimization problems (traveling salesman, shortest paths, matching, etc.) have spanning trees as their core structure. Several exact and approximate algorithms for these problems repeatedly solve minimum spanning tree (MST) instances. The fast and efficient polynomial-time algorithms existing for MST prove its effectiveness as a subroutine in solving these problems. Given an undirected graph $G = (N, A)$ with $n = |N|$ nodes and $m = |A|$ arcs and a weight w_{ij} associated with each arc $(i, j) \in A$, a spanning tree (T) is a connected acyclic subgraph that spans all the nodes. An MST (M) is the spanning tree of G with the minimum total weight of all constituent arcs. Figure 1(a) gives an example of an MST having a total weight of 55 represented by bold arcs (A_M). In this article, without loss of generality, we assume that all arc weights are distinct and as in all discussed properties and algorithms, ties can be broken arbitrarily.

The MST problem was first formally defined by Borůvka [1] in 1926 and since then it has drawn the attention of researchers. It arises in many applications either directly or indirectly. Some direct applications include designing computer and communication networks, power and leased-line telephone networks, piping in a flow network, wiring connections, and so on. In these problems, we aim to ensure a

viable path between each pair of nodes so that the total cost is minimized. Indirect applications include the all-pairs shortest path problem, network reliability, clustering and classification problems, and so on. In these applications, we either model the problem as an MST or try to find a substructure where its properties are utilized. We briefly explain some of these applications in the next section.

APPLICATIONS

Designing Physical Systems

Designing a physical system can be very complex, involving the interplay between multiple factors such as system performance, cost, and available technology. The major criterion in designing a network is usually either to physically connect geographically dispersed components, or to provide a channel for communication between the users. In most of these settings, the system needs to have the simplest possible connection without including any redundancies. This simple connection has the structure of a spanning tree, and it arises in numerous problem scenarios including the building of certain types of highways, computer networks, leased-line telephone networks, railroads, the installation of cable television lines or high-voltage electrical power transmission lines. Some typical problem settings are listed below in which spanning tree finds its application; however, more customized and problem-specific models can be developed for each scenario:

- when connecting terminals in cabling the panels of electrical equipment, the design should utilize the shortest possible length of wire;
- when constructing a pipeline network to connect a number of cities using the smallest possible length of pipeline;
- when linking isolated places in remote regions that are connected by roads,

Figure 1. Illustrating properties of spanning trees: (a) MST with $n - 1$ arcs; (b) adding arc $(1, 3)$ to the spanning tree forms a unique cycle $1-2-4-3-1$; (c) deleting arc $(3, 4)$ forms the cut $[S, \bar{S}]$ with $S = [1, 2, 4]$.

but not yet by telephone lines, we aim to determine along which stretches of roads we should place the telephone lines so that all areas are connected using the least possible total road miles;

- when constructing a digital computer system composed of high frequency circuitry, it is important to minimize the lengths of the wires between different components to reduce both capacitance and delay line effects and since the system must connect all the components, it reduces to a spanning tree problem;
- when connecting a number of computer sites by high speed lines, each line is available for leasing at a certain monthly cost, and we wish to determine a configuration that connects all the sites at the least possible cost.

Min-Max Paths

In a graph $G = (N, A)$ with arc weights w_{ij} , we define the value of a path P between a pair $[p, q]$ of nodes as the maximum weight arc in P . The min-max path problem determines the minimum value path from node p to node q . There are several real-life instances in which we solve all-pairs min-max path problems, determining the min-max paths for each pair of nodes. In designing the tracks or roads, one of the most critical factors is the change in elevation. In mountainous regions, this becomes even more important when determining the alignment of tracks. The change in elevation is very costly, as it increases the wear and tear associated with

braking. Besides, only trains with enough traction power can run in the regions with very high elevations. Therefore, we would like to find the paths between each pair of train stations that minimize the maximum elevation change. There are several other examples in which we solve the all-pairs min-max path problems: (i) in designing the trajectory of a spacecraft, we try to keep the maximum temperature to which its surface is exposed as low as possible; (ii) in designing wheelchair-accessible paths, we try to minimize the maximum ascent path segments; and (iii) in traveling through a desert, we want to minimize the maximum stretch between rest areas.

The all-pairs min-max paths problems can be easily solved by simply solving an MST instance. Let M be an MST of G , and P denote the unique path in M between a node pair $[p, q]$ with (k, l) as the maximum weight arc. Therefore, the value of path P is w_{kl} . Deleting the arc (k, l) divides the nodes into two subsets forming a cut $[S, \bar{S}]$. For example, in Fig. 1(c), deleting the arc $(3, 4)$ generates the cut $[S, \bar{S}]$, where $S = \{1, 2, 4\}$ and $\bar{S} = \{3, 5\}$. According to the strong cut property of an MST (discussed in the section titled “Properties of Minimum Spanning Trees”), the arc (k, l) is the minimum weight arc among all arcs in the cut $[S, \bar{S}]$. Then, consider any path P' between the node pair $[k, l]$ in G . It must contain an arc in $[S, \bar{S}]$ and, therefore, its value is at least w_{kl} . Because the path P in M is of value w_{kl} , it is the min-max path. This observation proves that the unique path between any pair $[k, l]$ of nodes is the min-max path in G .

Optimal Message Passing

An intelligence service agency has n agents located in an unfriendly country. Each agent knows a group of other agents and regularly passes messages to them using a special procedure. Each message between the agent pair (k, l) will fall into the hands of opponents with the probability of p_{kl} . These messages are very confidential and need to be passed with the minimum possible probability of being intercepted.

We can easily transform this problem into an MST instance. Consider each agent as a node and the medium of the message passing as an arc in the resulting graph G' . We need to determine a spanning tree T in G' that minimizes the probability of interception given by the expression $\{1 - \prod_{(k,l) \in T} (1 - p_{kl})\}$. Alternatively, we find a tree T that maximizes $\{\prod_{(k,l) \in T} (1 - p_{kl})\}$, or equivalently that maximizes $\{\sum_{(k,l) \in T} \log(1 - p_{kl})\}$. Therefore, it reduces to the problem of finding an MST in G' with an arc of weight $(-\log(1 - p_{kl}))$ between each node pair $[k, l]$. We add the negative sign to make the arc weights positive.

Clustering

Clustering is to partition a set of data into subsets or cluster such that the data points within a particular cluster should be more closely related to each other than the data points not in that cluster. Cluster analysis is important in a variety of disciplines such as medical and manufacturing that rely on empirical investigations. Suppose we need to find a partition of a set of n points in two-dimensional Euclidean space into clusters. Kruskal's algorithm explained in the following section is one of the most popular algorithms to solve this problem. As explained later, at each intermediate step, Kruskal's algorithm maintains a collection of node-disjoint trees and adds arcs in nondecreasing order of their lengths. The nodes spanned by these trees can be regarded as different clusters, which often provide excellent solutions for the clustering problem. We can also start from the MST and delete k arcs to find $k + 1$ clusters. The best partition can be found by simple visualization or by

defining an appropriate objective function. A good choice of an objective function depends on the underlying features of a particular clustering application. This analysis is not limited to points in two-dimensional space, and can be easily extended to multidimensional space by defining interpoint distances appropriately.

PROPERTIES OF MINIMUM SPANNING TREES

Some properties of spanning trees that are frequently used in the development of algorithms can be easily observed in Fig. 1: (i) each spanning tree has exactly $n - 1$ arcs; (ii) for every non-tree arc $(i, j) \in A/A_M$, the spanning tree T contains a unique path from node i to node j . Adding the arc (i, j) creates a cycle with this unique path; and (iii) deleting any arc (i, j) of the spanning tree partitions the graph G into two subsets.

These observations give rise to the two most important properties of MST, the building blocks of most of the algorithms: (i) strong cycle property and (ii) strong cut property. These properties are also referred to as *optimality conditions* for MST.

Theorem 1 [Strong Cut Property]. *A spanning tree M is an MST if and only if every MST arc $(i, j) \in A_M$ is the minimum weight arc in the cut formed by deleting the arc (i, j) .*

Proof. It is easy to show that every MST should satisfy this property. For, if $w_{ij} > w_{kl}$ and arc (k, l) is contained in the cut formed by deleting the arc (i, j) from M , then introducing arc (k, l) in place of arc (i, j) would create an MST of total weight less than M , contradicting the optimality of M . In Fig. 1(c), arc $(3, 4)$ has the minimum weight among all arcs in the cut formed by deleting it.

We now prove that, any spanning tree T^* , satisfying the property, is an MST. Suppose M is an MST and $T^* \neq M$. Therefore, T^* must contain an arc (i, j) that is not in M . Deleting

Figure 2. Finding MST using the strong cut property.

arc (i, j) from T^* forms the cut $[S, \bar{S}]$. Now, we add the arc (i, j) in M creating a unique cycle containing an arc (k, l) other than arc (i, j) , with $k \in S$ and $l \in \bar{S}$. As T^* satisfies strong cut property, $w_{ij} \leq w_{kl}$. However, M is an MST, so $w_{ij} \geq w_{kl}$, otherwise we can easily reduce the total weight by replacing the arc (k, l) by the arc (i, j) . Now, we introduce the arc (k, l) in T^* in place of the arc (i, j) , increasing the similarity between T^* and M by one more arc. By repeatedly replacing the uncommon arcs in T^* , we can transform it into the MST M , showing that T^* is also an MST. This completes the proof.

The strong cut property is utilized in deriving a simple algorithm that can transform any spanning tree T into an MST in a finite number of steps. We satisfy the property by investigating each cut one at a time, and appropriately deleting and adding arcs into the tree. Figure 2(a)–(f) illustrates the transformation of an arbitrary tree to an MST. The highlighted arcs represent the spanning tree at each stage and the arrow points to the minimum weight arc in the cut $[S, \bar{S}]$. Figure 2(a) shows a spanning tree of weight

125 and in the next four iterations, the arc with minimum weight in the cut being examined replaces the arc violating the strong cut property. We reach the MST of weight 55 in a finite number of steps, but the running time is not very attractive. However, it builds the foundation of Kruskal's algorithm [2], discussed in the following section, which improves the complexity by systematically analyzing each cut.

Theorem 2 [Strong Cycle Property]. *A spanning tree M is an MST if and only if every non-tree arc $(i, j) \in A/A_M$ is the maximum weight arc in the cycle, uniquely created by introducing the arc (i, j) in M .*

The proof is similar to Theorem 1, and details can be found in Ref. 3.

We can also derive a very simple algorithm using the strong cycle property. We start from an arbitrary spanning tree, and then verify the strong cycle property for each cycle created by adding a non-tree arc to the spanning tree. If any cycle does not satisfy the property, we replace the existing arc with the lower weight arc present in the cycle and thereby reduce the weight of the tree. This illustration is shown in Fig. 3(a)–(f) starting with the

Figure 3. Finding MST using the strong cycle property.

same spanning tree considered in Fig. 2(a). In the next four iterations, we create a cycle by adding a non-tree arc and then reducing the total weight by deleting the arc of maximum weight among all arcs in the cycle. Although we finally achieve the MST, the steps of creating cycles and deleting maximum weight arcs are not time efficient. Prim [4] utilizes these properties to develop an efficient algorithm, which is discussed in a subsequent section.

We have described two fundamental properties that form the basis of most of the MST algorithms. In this article, we present two classical algorithms in detail, with an overview of recent advances: (i) Kruskal's algorithm and (ii) Prim's algorithm.

KRUSKAL'S ALGORITHM (1956)

Kruskal's algorithm is based on the strong cycle property of MSTs. We generate an MST from scratch by maintaining a forest of trees at each step. The basic algorithm is given below:

Step 1. Sort all arcs in the nondecreasing order of their weights.

Step 2. Initialize the list of arcs, *CURRENT*, which contains the current set of arcs in MST to *NULL*.

Step 3. Examine arcs in their sorted order one at a time; add an arc to the *CURRENT* list if it does not create a cycle with the arcs already present in it. Examining the arcs in their sorted order helps in maintaining the strong cycle property.

Step 4. Terminate the algorithm when the cardinality of the list becomes $n - 1$; that is $|CURRENT| = n - 1$.

We illustrate Kruskal's algorithm in Fig. 4 by running it on the example given in Fig. 1(a). We also explain how the strong cycle property forms the base of the algorithm. As given in Step 1, we first sort all arcs in the nondecreasing order of their weights: $\{(2, 4), (3, 4), (1, 2), (1, 3), (3, 5), (2, 3), (3, 4), \text{ and } (4, 5)\}$. In Fig. 4(a) there are five disconnected sets, each containing one node. In the first three iterations, the algorithm adds the arcs $(2, 4)$, $(3, 4)$, and $(1, 2)$

Figure 4. Illustration of Kruskal's algorithm.

to *CURRENT*, respectively, as shown in Fig. 4(b)–(d). As we examine them in sorted order, each newly added arc has a lower weight than the maximum weight arc among all the possible cycles, which contain nodes that it is joining. For example, in Fig. 4(b), arc (2, 4) has a weight lower than the maximum weight arc in any cycle containing nodes 2 and 4. In the next iteration, the algorithm examines and discards arc (1, 3) as it creates a cycle. It can be observed that adding arc (1, 3) violates the strong cycle property, as it has the maximum weight in the cycle 1-2-4-3. Finally, the arc (3, 5) is added to *CURRENT* and the algorithm terminates as the cardinality becomes four. It can be observed that at each stage the strong cycle property is maintained. This forms the basis of the proof of correctness.

The correctness of Kruskal's algorithm follows from the fact that at each step we include the minimum weight arc in the tree, while discarding those arcs that create a unique cycle. As arcs are examined in the nondecreasing order of their weights, any discarded arc has a maximum weight among all arcs already present in the cycle formed by its addition.

Complexity Analysis

Kruskal's algorithm maintains a forest of trees in *CURRENT* at each step. For example, the set *CURRENT* that corresponds to Fig. 2(c) comprises three trees containing nodes {1}, {2, 3, 4}, and {5}. At each step, a new arc is put in *CURRENT* if it connects distinct trees (i.e., no cycle). Hence, the algorithm requires repetitive applications of two basic operations, commonly known as *union-find* operations [5]. The *find* operation returns the lists (trees) to which an arc belongs, and the *union* operation merges the two lists (trees). Several data structures have been proposed for these operations having different complexities.

We first discuss the implementation of Kruskal's algorithm, which runs in $O(m + n \log n)$ time, besides taking $O(m \log m) = O(m \log n^2) = O(m \log n)$ time for sorting all arcs. We maintain a set of singly linked lists, $T_1, T_2, \dots$, each containing the nodes of the tree in the forest maintained by the algorithm. We also maintain the cardinality and the last node of each list L in $card(L)$, and $last(L)$, respectively. We associate an index $first(i)$ for each node i , which records the first node of the list

containing the node i . For example, the list T_2 stores the second tree of nodes $\{2, 3, 4\}$ in Fig. 2(c): $\text{card}(T_2) = 3$; $\text{last}(T_2) = 4$; and $\text{first}(2) = \text{first}(3) = \text{first}(4) = 2$.

Each *find* operation takes $O(1)$ time using this data structure. To check any arc (k, l) , we compare $\text{first}(k)$ and $\text{first}(l)$. If they are equal, k and l belong to the same tree and the arc (k, l) cannot be added; otherwise, they belong to different trees. In a worst-case scenario, all arcs are checked, requiring a total of $O(m)$ time. If the arc (k, l) is to be added, we need to merge two trees: $T_1 = \text{find}(k)$ and $T_2 = \text{find}(l)$. Without a loss of generality, assume that $\text{card}(T_1) > \text{card}(T_2)$. While merging, we put the larger list T_1 first and append the smaller list T_2 with the last node [determined by $\text{last}()$] of T_1 . Thereafter, we update the (i) cardinality of the new list requiring $O(1)$ time; (ii) last node of the new list requiring $O(1)$ time; and (iii) first-node-index of all nodes that were originally contained in T_2 requiring $O(\text{card}(T_2))$. Hence, each union operation takes $O(h)$ time, where $h = \text{card}(T_2)$. It can be easily proven by induction that the total time taken by all union operations to create a list of size n in the worst case is $O(n \log n)$. Therefore, Kruskal's algorithm takes $O(m)$ time for all *find* operations, $O(n \log n)$ time for all *union* operations, and $O(m \log n)$ for sorting all arcs summing up to $O(m + (m + n) \log n) = O(m \log n)$.

With the development of new data structures, several authors have significantly improved the running time of the classical or modified Kruskal's algorithm [6]. The Fliter–Kruskal algorithm [7] reduces the running time to $O(m + n \log n \log m/n)$, which is very close to linear for a not very sparse graph. We briefly discuss some more algorithms in the section titled “Recent Algorithms.” In the next section, we describe another extensively studied algorithm, which was first developed by Jarnik [8] in 1930, and later independently by Prim [4] in 1957, and by Dijkstra [9] in 1959.

Therefore, it is known as Jarnik–Prim's, Prim's, or Dijkstra–Jarnik–Prim's (DJP) algorithm.

PRIM'S ALGORITHM (1930/1957/1959)

Prim's algorithm is based on the strong cut property of MSTs. Similar to Kruskal's algorithm, we build an MST starting from a single node and adding one arc at a time. However, in Prim's algorithm, a single tree T spanning on a subset S of nodes is maintained instead of a forest. The basic algorithm is given below:

Step 1. Initialize a set S and the current spanning tree T with node 1 (arbitrarily chosen). Initialize set $\bar{S}$ by inserting all nodes except $\{1\}$ in it, that is, $S = \{1\}$ and $\bar{S} = N \setminus \{1\}$.

Step 2. Find the arc (i, j) with the minimum weight among all arcs in the cut $[S, \bar{S}]$ such that $i \in S$ and $j \in \bar{S}$. Add arc (i, j) in tree T and move node j from set $\bar{S}$ to set S . This step directly follows from the strong cut property of an MST.

Step 3. If $|S| = n$, T is an MST, stop; otherwise, go to Step 2.

We illustrate Prim's algorithm in Fig. 5 on the same example, shown in Fig. 1(a), which was used earlier to explain Kruskal's algorithm. As given in Step 1, set $S = \{1\}$ and $\bar{S} = \{2, 3, 4, 5\}$. The cut set $[S, \bar{S}]$ contains two arcs $(1, 2)$ and $(1, 3)$ [see Fig. 5(b)]. The algorithm selects the arc having the least weight, that is arc $(1, 2)$. Now, set $S = \{1, 2\}$, T contains the arc $(1, 2)$, and the cut set $[S, \bar{S}]$ comprises arcs $(1, 3)$, $(2, 3)$, $(2, 4)$, and $(2, 5)$. In the next step, the algorithm selects the arc $(2, 4)$ because it has the minimum weight and updates all sets [see Fig. 2(c)]. In the next two iterations, as shown in Fig. 2(d) and (e), the algorithm chooses the arcs $(3, 4)$ and $(3, 5)$, respectively. The final MST produced

by the algorithm is shown in Fig. 2(f). It can be easily observed that each newly added arc has the minimum weight among all arcs in the cut that was obtained by deleting that arc. For example, in Fig. 5(c), arc (2, 4) has the lowest weight among all arcs, $\{(1, 3), (2, 3), (2, 5), \text{ and } (2, 4)\}$, joining the cut $\{1, 2\}$ and $\{3, 4, 5\}$.

The correctness of the algorithm can be shown through induction by proving that at each step the spanning tree T is an MST of nodes present in the set S . At the start, T contains only one node, so it is a trivial MST. Assume that T is an MST just before adding a new arc (k, l) , where $k \in S$ and $l \in \bar{S}$, and a final MST (M) is consistent with T so far (i.e., A_T is a subset of A_M). If the arc (k, l) is in M , new T is obviously an MST; otherwise, introducing it in M forms a unique cycle W with some nodes of S and some nodes of $\bar{S}$. The cycle W must contain one arc (p, q) connecting set S and $\bar{S}$ other than arc (k, l) . From Prim's algorithm, we know that $w_{kl} \leq w_{pq}$, and because M is an MST we have $w_{kl} \geq w_{pq}$, together implying that $w_{kl} = w_{pq}$. Therefore, T is a tree with exactly the same total weight as M containing the same set

of nodes. It proves the inductive hypothesis showing the correctness of Prim's algorithm.

Complexity Analysis

Prim's algorithm performs $n - 1$ iterations of Step 2 of the basic algorithm, each adding one arc at a time to the current tree until it becomes an MST containing $n - 1$ arcs. In each iteration, the selected arc has the minimum weight in the cut $[S, \bar{S}]$. A simple yet expensive way of selecting the minimum weight arc is to scan the entire set of arcs in $O(m)$ time. Therefore, the total running time of this algorithm is $O(nm)$. We can substantially improve the running time by efficiently choosing the entering arc (minimum weight arc) using various types of *heaps* (a specialized tree-based data structure), such as the binary heap and Fibonacci heap. A binary heap (Fig. 6) is created using a binary tree with two main properties: (i) it is almost a complete binary tree, that is all levels of the tree except the last one must be fully filled, and if the last level is not complete then the nodes of that level are filled from left to right and (ii) each node's value is greater than or equal to that of each of its children. We briefly

Figure 5. Illustration of Prim's algorithm.

Figure 6. A binary heap with five elements.

explain the operations supported by a heap containing a collection H of objects and their use in Prim's algorithm (Fig. 7).

create-heap(H): Creates an empty heap H .

find-min(H): Returns an object of minimum key from H . Each object corresponds to a node j and its key equals the distance label $d(j)$. It facilitates choosing the minimum weight arc in the cut

$[S, \bar{S}]$, which is the bottleneck element of Prim's algorithm. The distance label $d(j)$ represents the minimum weight of all arcs in the cut $[S, \bar{S}]$ incident to any node j in $\bar{S}$ from any node in S , that is $d(j) = \min\{w_{ij} : (i, j) \in [S, \bar{S}]\}$. For example, in Fig. 5(d), $d(3) = 10$ as among all arcs in the cut $[S, \bar{S}]$ incident to node 3, $\{(1, 3), (2, 3), \text{ and } (4, 3)\}$, the arc $(4, 3)$ has the minimum weight of 10.

insert(H): Inserts a new object i with a predefined key into H .

decrease-key($i, value, H$): Reduces the key of object i to $value$. As new nodes are inserted into set S , the distance labels may decrease due to a new set of arcs in the cut $[S, \bar{S}]$. For example, in Fig. 5(c), $d(3) = 20$ and after inserting node 4 in S , $d(3)$ decreases to 10.

delete-min(i, H): Deletes an object i with minimum key from H . It corresponds to

```

algorithm Prim
begin
    create heap( );
    for each  $j \in N - \{1\}$  do  $d(j) := C + 1$ ; //  $C$  is the maximum arc weight in graph  $G$ .
    set  $d(1) := 0$ ; and  $pred(1) := 0$ ;
    for each  $j \in N$  do insert( $j$ );
     $T := \emptyset$ ;
    while  $|T| < (n - 1)$  do
        begin
            find min( $i$ );
            delete min( $i$ );
             $T := T \cup (pred(i), i)$ ;
            For each  $(i, j) \in A(i)$  with  $j \notin T$  do
                If  $d(j) > w_{ij}$  then
                    begin
                         $d(j) := w_{ij}$ ;
                         $pred(j) := i$ ;
                        decrease key( $j, w_{ij}$ );
                    end;
            end;
         $T$  is an MST.
    end;

```

Figure 7. Prim's algorithm based on heap data structure.

Table 1. Running Time of Prim’s Algorithm with Various Data Structures

Data Structure	Running Time
Adjacency matrix [6]	$O(n^2)$
Binary heap,	$O(m \log n)$
Adjacency list [6]	
d -heap [6]	$O(m \log_d n)$, with $d = \max\{2, m/n\}$
Fibonacci heap [6]	$O(m + n \log n)$
Johnson’s data	$O(m \log \log C)$
structure [10]	
Thorup <i>et al.</i> [11]	$O(m + n \log \log \min(n, C))$

the transfer of a node from set S to set $\bar{S}$. At each step, H contains all elements of set $\bar{S}$.

It is clear that Prim’s algorithm performs insert, find-min, and delete-min operations at most n times and the decrease-key operation at most m times. The time bound for each operation, and consequently the total running time of the algorithm, varies with the type of heap. A binary heap supports insertion in $O(\log n)$, find-min in $O(1)$, and delete-min in $O(\log n)$; thereby taking a total time of $O(n + 2n \log n) = O(n \log n)$. At most, $O(m \log n)$ time is consumed in m decrease-key operations each requiring $O(\log n)$ time. Therefore, implementing Prim’s algorithm using a binary heap takes $O(n \log n + m \log n) = O(m \log n)$ time. Table 1 gives the running time of the algorithm with various types of heaps.

RECENT ALGORITHMS

The criticality of an MST—due to its direct and indirect applications in almost all network flow problems—has always inspired researchers to find faster algorithms. With the development of novel data structures, new implementation schemes are being constructed. The primary aim of these schemes is to improve the asymptotic running time of the algorithm. We list the recent advances

Table 2. Recent Advances in the MST Algorithms

Algorithms	Running Time
Yao [16]	$O(m \log \log n)$
Cheriton and Tarjan [17]	$O(m \log \log n)$
Karger [18]	$O(n \log n + m)$
Fredman and Tarjan [19]	$O(m \beta(m, n))^a$
Gabow <i>et al.</i> [20]	$O(m \log \beta(m, n))$
Osipov <i>et al.</i> [7]	$O(m + n \log n \log m/n)$
Chazelle [21]	$O(m \alpha(m, n))^b$
Karger <i>et al.</i> [15]	$O(\min(n^2, m \log n));$ average: $O(m)$

Fredman and Willard [23]	$O(m + n \log n / \log \log n)$

^a $\beta(m, n) = \min(i : \log^{(i)} n \leq m/n)$, and $\log^0 n = n$.

^b $\alpha(m, n)$, inverse Ackermann’s function [24].

in Table 2. The details of these algorithms can be found in corresponding papers and with a summarized analysis in Refs 12, 13, and 14. The randomized algorithm by Tarjan *et al.* [15] finds the MST within linear time with very high probability of $1 - \exp(-\Omega(m))$; however, its worst-case complexity is $O(\min(n^2, m \log n))$, which is same as Borůvka’s algorithm [1].

SUMMARY

The MST problems are generally recognized as one of the first combinatorial optimization problems studied specifically from an algorithmic perspective. Its diverse set of direct and indirect applications has always encouraged researchers to improve the preexisting algorithms. Several variants of MST are being extensively studied; some of which are NP-complete, while for others polynomial-time algorithms exist. For example, (i) *k*-minimum spanning tree problem: to find a tree that spans any set of k nodes and has a minimum total weight; (ii) *capacitated MST problem*: to find an MST honoring a set of capacity constraints; (iii) *Euclidean MST problem*: to find an MST in a graph with arc weights corresponding to the Euclidean

distance between nodes; and (iv) *p-smallest spanning tree problem*: to find a set of p spanning trees such that no spanning tree outside this set has a lesser weight. The first two problems are NP-complete, while polynomial-time algorithms exist for the rest.

In this article, we have discussed two central properties of MST, which are at the core of all existing algorithms: strong cut and strong cycle properties. We have also described two classical algorithms based on these properties: Kruskal's algorithm (strong cycle) and Prim's algorithm (strong cut). We have also listed a set of leading contributions in this area, which have reached very close to linear time complexity. We have emphasized, with some examples, that running times of the algorithms can be improved significantly by using advanced data structures.

Even after 80 years of research on the MSTs, it remains an open problem to determine whether or not there exists a deterministic algorithm with a linear time bound for a graph with general arc weights. Pettie and Ramachandran [22] have developed a provably optimal deterministic algorithm, but its complexity is still unknown. There are also some research opportunities in developing parallelizable algorithms, as most of the existing ones are not very effective.

Humboldt–Universität zu Berlin,
Berlin, Germany

INTRODUCTION

The general form of an MINLP is

$$\begin{array}{ll} \text{minimize} & f(x,y) \\ \text{subject to} & g(x,y) \leq 0 \\ & x \in X \\ & y \in Y \text{ integer.} \end{array} \quad (\text{P})$$

The function $f: \mathbb{R}^{n+s} \rightarrow \mathbb{R}$ is a possibly nonlinear objective function and $g: \mathbb{R}^{n+s} \rightarrow \mathbb{R}^m$ a possibly nonlinear constraint function. Most algorithms require the functions f and g to be continuous and differentiable, but some may even allow for singular discontinuities. The variables x and y are the decision variables, where y is required to be integer valued. The sets $X \subseteq \mathbb{R}^n$ and $Y \subseteq \mathbb{R}^s$ are bounding-box-type restrictions on the variables. In addition to integer requirements on variables, other kinds of discrete constraints are also commonly used. These are, for example, special-ordered-set constraints [only one (SOS type 1) or two consecutive (SOS type 2) variables in an (ordered) set are allowed to be nonzero] [1], semicontinuous variables (the variable is allowed to take either the value zero or a value above some bound), semiinteger variables (like semicontinuous variables, but with an additional integer restriction), and indicator variables (a binary variable indicates whether a certain set of constraints has to be enforced). In all cases, it is possible to reformulate such constraints into a standard form by introducing additional

variables and linear constraints. The purely continuous case ($s = 0$) is not considered here; see the article titled **Software for Nonlinearly Constrained Optimization** in this encyclopedia for an overview on NLP Software.

Computational tractability depends significantly on whether the functions $f(x,y)$ and $g(x,y)$ are convex or not; In this article, we say an MINLP is *convex* if both $f(x,y)$ and $g(x,y)$ are convex over $X \times Y$. Otherwise the MINLP is said to be *nonconvex*. Note that some solvers for convex MINLPs can also be applied under less strict notions of convexity, for example, to the case where the set defined by the constraints $g(x,y) \leq 0$ is convex, or where the objective function and constraints are only pseudoconvex [2]. (A differentiable function $h: X \rightarrow \mathbb{R}$ is *pseudoconvex* on a convex set $X \subseteq \mathbb{R}^n$ if for every $x, y \in X$ with $h(x) < h(y)$, it follows that $\langle \nabla h(y), x - y \rangle < 0$. An important property of a pseudoconvex function is the convexity of its level-sets.)

HISTORY

To the best of our knowledge, the earliest commercial software package that could solve MINLP problems was SCICONIC in the mid-1970s [3–5]. Rather than handling nonlinearities directly, linked special-ordered-set variables provided a mechanism to represent low dimensional nonlinear terms by a piecewise linear approximation and thus allowed to use mixed-integer linear programming (MIP) to obtain solutions to an approximation of the MINLP. In the mid-1980s, Grossmann and Kocis developed DICOPT, a general purpose algorithm for convex MINLP, based on the outer approximation method [6]. Since then, a number of academic and commercial codes for convex MINLP have emerged, either based on outer approximation using MIP relaxations [6], an integration of outer approximation into a linear programming (LP) relaxation based branch and cut [7],

or nonlinear programming (NLP) relaxation based branch-and-bound algorithms [8]. For the global solution of nonconvex MINLP, the first general purpose solvers were ALPHABB, BARON, and GLOP, all based on convexification techniques for nonconvex constraints [9–12]. See also the section titled “Algorithms” for a small discussion of MINLP algorithms.

GROUPINGS

Embedded versus Independent

Due to the high complexity of MINLP and the wide range of applications that can be modeled as MINLPs, it is sometimes desirable to customize the MINLP solver for a specific application in order to achieve good computational performance [13–15]. Further, MINLP solvers are often built by combining LP, MIP, and NLP solvers. These are two main reasons for tightly integrating some MINLP solvers into modeling systems (general systems like AIMMS [16], AMPL [17], and GAMS [18] or vendor specific systems like FICO XPRESS-MOSEL [19], LINGO [20], and OPL [21]). For example, the AIMMS outer approximation solver (AOA) allows modifications of its algorithm by the user. Further, the solvers DICOPT and SBB are exclusively available for GAMS users, since they revert to MIP and NLP solvers in the GAMS system for the solution of subproblems. Also for an efficient use of the solver OQNLP, it is preferable to use one of the GAMS NLP solvers.

On the other side, there are many solvers that can be used independent of a modeling system, even though they may still require the presence of an LP, MIP, or NLP solver plugin. However, often these “independent” solvers are also used within a modeling system, since the modeling system typically provides evaluators for nonlinear functions, gradients, and Hessians and gives easy access to algebraic information about the problem.

Extending MIP versus Extending NLP versus Starting from Scratch

MINLP solvers are seldom developed completely from scratch. In many cases, an

MIP or NLP solver builds the basis for an extension toward MINLP. Solvers which can be categorized as extending an MIP solver toward handling of nonlinear objectives and constraints are BONMIN, COUENNE, CPLEX, FICO XPRESS-OPTIMIZER, FILMINT, LINDOBB, MOSEK, and SCIP. On the other hand, solvers where an NLP solver was extended to handle integrality restrictions are BNB, FICO XPRESS-SLP, FMINCONSET, KNITRO, MILANO, MINLP_BB, MISQP, OQNLP, and SBB.

Finally, there is a group of solvers which are more-or-less developed from scratch, but which may solve LP, MIP, NLP, or MINLP subproblems. In this category, we have ALPHABB, ALPHAECF, AOA, BARON, DICOPT, LAGO, LINDOGLOBAL, and MIDACO.

Algorithms

Algorithms for solving MINLPs are often build by combining algorithms from linear programming, integer programming, and nonlinear programming, for example, branch-and-bound, outer approximation, local search, and global optimization. We refer to the sections titled “Fundamental Techniques,” “Nonlinear Programming (NLP) and Global Optimization (GO),” and “Models and Algorithms” in this encyclopedia for an introduction into these topics.

Most of the solvers implement one (or several) of three algorithmic ideas to tackle MINLPs. First, there are branch-and-bound solvers that use NLP relaxations such as ALPHABB, BNB, BONMIN (in B-BB mode), CPLEX, FICO XPRESS-OPTIMIZER, FICO XPRESS-SLP (in “SLP within MIP” mode), FMINCONSET, KNITRO, LINDOBB, MILANO, MINLP_BB, MOSEK, and SBB. For all these solvers except ALPHABB, the NLP relaxation is obtained by relaxing the integrality restriction in (P), thus, it may be a nonconvex NLP. Since the NLP solver used to solve the NLP relaxation usually ensures only local optimal solutions, these solvers work as heuristics in case of a nonconvex MINLP. For the solver ALPHABB, however, a convex NLP relaxation is generated by using convex underestimators for the functions $f(x,y)$ and

$g(x,y)$ in (P). This solver can therefore be applied also to nonconvex MINLPs.

As an alternative to relaxing integrality restrictions and keeping nonlinear constraints, some solvers keep the integrality constraints and instead replace the nonlinear functions $f(x,y)$ and $g(x,y)$ by a linear relaxation. In an outer-approximation algorithm [6,22], a relaxation is obtained by using gradient-based linearizations of $f(x,y)$ or $g(x,y)$ at solution points of NLP subproblems. The resulting MIP relaxation is then solved by an MIP solver. Solvers in this class are AOA, BONMIN (in B-OA mode), DICOPT, and FICO XPRESS-SLP (in “MIP within SLP” mode). Since gradient-based linearizations yield an outer-approximation only for convex MINLPs, these solvers are only applicable for convex MINLPs. In contrast to outer-approximation based algorithms, an extended cutting-plane algorithm solves a sequence of MIP relaxations which encapsulate optimal solutions of (P) by cutting-planes and supports of $f(x,y)$ rather than outer-approximating the whole feasible region of (P) [23]. This algorithm is implemented by the solver ALPHAECP, that can be applied to convex as well as pseudoconvex MINLPs.

A third class of solvers are those which integrate the linearization of $f(x,y)$ and $g(x,y)$ into the branch and cut process [7]. Thus, here an LP relaxation is successively solved, new linearizations of $f(x,y)$ and $g(x,y)$ are generated to improve the relaxation, and integrality constraints are enforced by branching on the y variables. Solvers which use gradient-based linearizations are AOA, BONMIN (in B-QG mode), and FILMINT.

Since the use of gradient-based linearizations in a branch and cut algorithm ensures global solutions only for convex MINLPs, solvers for nonconvex MINLPs use convexification techniques to compute linear underestimators of a nonconvex function. However, the additional convexification step may require to branch also on continuous variables in nonconvex terms (so called *spatial* branching). Such a branch and cut algorithm is implemented by

BARON, COUENNE, LAGO, LINDOGLOBAL, and SCIP.

The remaining solvers implement a different methodology. BONMIN (in B-Hyb mode) alternates between LP and NLP relaxations during one branch-and-bound process. MISQP integrates the handling of integrality restrictions into the solution of a nonlinear program via sequential quadratic programming, that is, it ensures that $f(x,y)$ and $g(x,y)$ are only evaluated at points where y is integral. MIDACO applies an extended ant colony optimization method and can use MISQP as a local solver. Finally, OQNLP applies a randomized approach by sampling starting points and fixings of integer variables for the solution of NLP subproblems.

Capabilities

Not every solver accepts general MINLPs as input. Solvers that currently handle only MINLPs, where the objective function and constraints are quadratic (so-called *MIQCPs*) or second order cone (SOC) programs are CPLEX, FICO XPRESS-OPTIMIZER, MOSEK, and SCIP. All solvers support convex quadratic functions. Further, nonconvex quadratic functions that involve only binary variables are supported by CPLEX and FICO XPRESS-OPTIMIZER. Quadratic constraints that permit a SOC representation are supported by CPLEX. SOC constraints are supported by MOSEK. SCIP supports quadratic constraints in any form.

Solvers that guarantee global optimal solutions for convex general MINLPs are ALPHAECP, AOA, BNB, BONMIN, DICOPT, FICO XPRESS-SLP, FILMINT, FMINCONSET, KNITRO, LAGO, LINDOBB, MILANO, MINLP_BB, and SBB. In case of a nonconvex MINLP, these solvers can still be used as a heuristic. Especially branch-and-bound based algorithms that use NLPs for bounding, often find good solutions also for nonconvex problems, while pure outer approximation based algorithms may easily run into infeasible LP or MIP relaxations due to wrong cutting-planes. Note, that ALPHAECP ensures global optimal solutions also for pseudoconvex MINLPs.

Solvers that also guarantee global optimality for nonconvex general MINLPs require an algebraic representation of the functions $f(x,y)$ and $g(x,y)$ for the computation of convex underestimators. That is, for each function a representation as a composition of basic arithmetic operations and functions (addition, multiplication, power, exponential, trigonometric, etc.) on constants and variables need to be provided. The solvers ALPHABB, BARON, COUENNE, and LINDOGLOBAL belong into this category.

MIDACO, MISQP and OQNLP can handle general MINLPs, but do not guarantee global optimality even on convex problems.

MINLP SOLVERS

In the following, we briefly discuss individual solvers for MINLPs. We have excluded solvers from this list that are clearly no longer available (e.g., SCICONIC). The solvers listed below have different levels of reliability and activity with respect to development and maintenance. Wide availability through modeling systems and other popular software indicates that a solver has reached a decent level of maturity. Hence, in this list, we mention availability (e.g., open source, standalone binary, interfaces to general modeling systems) in addition to a solver's developer, capability, and algorithmic details. Table 1 summarizes the list of solvers and indicates the availability via AIMMS, AMPL, GAMS, and the NEOS server for each solver [43].

ALPHABB (α -Branch-and-Bound) [9,29]. This solver has been developed by the research group of C. A. Floudas at the Computer-Aided Systems Laboratory of Princeton University. It is available to this group and to their collaborators.

ALPHABB can be applied for convex and nonconvex MINLPs. It implements a branch-and-bound algorithm that utilizes convex NLPs for bounding. Convex envelopes and tight convexifications are obtained for specially structured nonconvex terms (e.g., bilinear, trilinear, multilinear, univariate concave, edge concave,

generalized polynomials, and fractional), and α -convex underestimators for general twice continuously differentiable functions. The latter are determined by adding a nonpositive convex function to the original nonconvex function such that the Hessian of the sum is guaranteed to be positive semidefinite (PSD) [51]. Various interval arithmetic based techniques for estimating rigorous bounds on the minimal eigenvalue of the Hessian of the original nonconvex function are available.

ALPHAIECP (α -Extended Cutting-Plane) [2,30]. This solver has been developed by the research group of T. Westerlund at the Process Design and Systems Engineering Laboratory of the Åbo Akademi University, Finland. It is available as a commercial solver within GAMS.

ALPHAIECP ensures global optimal solutions for convex and pseudoconvex MINLPs. It generates and successively improves an MIP outer approximation of a neighborhood of the set of optimal solutions of (P) and can solve NLP subproblems to find feasible solutions early. The MIP is here refined by linearizing nonlinear constraints at solutions of the MIP outer approximation. By shifting hyperplanes, pseudoconvex functions can also be handled.

AOA (AIMMS Outer Approximation) [16]. This solver has been developed by Paragon Decision Technology. AOA is available as an "open solver" inside AIMMS. The open solver approach allows the user to customize the algorithm for a specific application.

AOA ensures global optimal solutions only for convex MINLPs. It generates and successively improves an MIP outer approximation of (P) and can solve NLP subproblems to find feasible solutions early. In contrast to ALPHAIECP, AOA constructs an MIP outer approximation of the feasible region of (P) by linearizing nonlinear functions in solutions of NLP subproblems [6]. Since for a nonconvex constraint such a linearization may not be valid, the MIP relaxation is modified such that the corresponding hyperplane is allowed to move away from its support point.

Table 1. An Overview on Solvers for MINLP. The First Row Indicates Whether a Solver Accepts Only Problems with Quadratic Functions (MIQCPs) or General Nonlinear Functions (MINLPs)

^aInterface for MINLPs available, but not included in GAMS distribution.

Recently, also a branch-and-bound algorithm that utilizes LPs for bounding [7] has been added to AOA.

BARON (Branch-And-Reduce Optimization Navigator) [12,31]. This solver was originally developed by the group of N.V. Sahinidis at the University of Illinois at Urbana-Champaign and is currently developed by N.V. Sahinidis at Carnegie Mellon University and M. Tawarmalani at Purdue University. It is available as a commercial solver within AIMMS and GAMS.

BARON can be applied to convex and nonconvex MINLPs. It implements a spatial branch-and-bound algorithm that utilizes LPs for bounding. The linear outer-approximation is based on a reformulation of (P) that it constructed (by adding auxiliary variables) in a way that it contains only nonconvex terms for which a convex underestimator (or concave overestimator) is known. The algorithm is enhanced by using advanced box reduction techniques and new convexification techniques for multilinear terms [52]. Further, BARON is able to use NLP relaxations for bounding [44], even though this option is not encouraged.

BNB (Branch and Bound) [32]. This solver has been developed by K. Kuipers of the Department of Applied Physics at the University of Groningen. It is available as MATLAB [53] source.

BNB ensures global optimal solutions for convex MINLPs. It implements a branch-and-bound algorithm utilizing nonlinear relaxations for the bounding step [8]. The NLPs are solved by the MATLAB Optimization Toolbox routine `FMINCON`.

BONMIN (Basic Open-source Nonlinear Mixed Integer Programming) [33]. This open-source solver has been developed primarily by P. Bonami in a cooperation of Carnegie Mellon University and IBM Research. It is available in source code and as standalone binaries from COIN-OR (Computational Infrastructure for Operations Research) [54], has an AMPL interface, and is distributed as a free solver within GAMS.

BONMIN ensures global optimal solutions only for convex MINLPs. It implements (at

least) four algorithms: B-OA is an outer-approximation algorithm that generates and successively improves an MIP outer approximation of (P) [6], B-QG is a branch-and-bound algorithm that utilizes LPs for bounding [7], B-BB is a branch-and-bound algorithm that utilizes NLPs for bounding [8], and B-Hyb is a hybrid of B-QG and B-BB, which alternates between LP and NLP relaxations for bounding. BONMIN is implemented on top of the MIP solver CBC [55] and can use FILTERSQP [56] and IPOPT [57] as NLP solvers.

COUENNE (Convex Over and Under ENvelopes for Nonlinear Estimation) [34]. This open-source solver has been developed primarily by P. Belotti, originally in cooperation of Carnegie Mellon University and IBM Research, and now at Lehigh University. It is available in source code and as standalone binaries from COIN-OR, has an AMPL interface, and is distributed as a free solver within GAMS.

COUENNE ensures global optimal solutions for convex and nonconvex MINLPs. It implements a spatial branch-and-bound algorithm that utilizes LPs for bounding. Similar to BARON, the linear outer-approximation is generated from a reformulation of (P). The algorithm is enhanced by box reduction techniques and disjunctive cuts [58]. COUENNE is implemented on top of BONMIN.

CPLEX [24]. This solver has been developed by CPLEX Optimization, Inc. (later acquired by ILOG and recently acquired by IBM). It is available as standalone binaries and as a component in many modeling systems.

CPLEX can solve convex MIQCPs. For models that only have binary variables in the potentially indefinite quadratic matrices, CPLEX automatically reformulates the problem to an equivalent MIQCP with PSD matrices. It implements a branch-and-bound algorithm that utilizes LPs or QCPs for bounding.

DICOPT (Discrete and Continuous Optimizer) [18,35]. This solver has been developed by the research group of I. E. Grossmann at the Engineering Research Design Center at Carnegie Mellon University. It is available as a commercial solver within GAMS.

DICOPT ensures global optimal solutions for convex MINLPs. Starting with the NLP relaxation (obtained from (P) by relaxing the integer requirement on y), it alternates between solving MIP outer approximations and NLP subproblems of (P) to compute lower and upper bounds [6]. To accommodate nonconvex MINLPs, nonlinear equality constraints are relaxed by replacing them with inequalities where the linearizations of the nonlinear functions are allowed to move away from their support point by the use of slack variables and through an augmented penalty function in the MIP relaxation. Since in this case valid lower bounds cannot be obtained, the termination is based on lack of improvement in the objective of the NLP subproblem.

FICO XPRESS-OPTIMIZER [25]. This solver has been developed by Dash Optimization (later acquired by FICO). It is available as standalone binaries and as a component in many modeling systems.

FICO XPRESS-OPTIMIZER can solve convex MIQCPs. For models that only have binary variables in the potentially indefinite quadratic matrices, FICO XPRESS-OPTIMIZER automatically reformulates the problem to an equivalent MIQCP with PSD matrices. It implements a branch-and-bound algorithm that utilizes QCPs for bounding.

FICO XPRESS-SLP [36]. This solver has been developed by Dash Optimization (later acquired by FICO). It is available as standalone binaries and as a FICO XPRESS-MOSEL module [19].

FICO XPRESS-SLP ensures global optimal solutions for convex MINLPs. It implements three algorithms: The (default) “SLP within MIP” variant is a branch-and-bound algorithm that utilizes NLPs for bounding [8]. The NLP subproblems are solved by successive linear programming (SLP). Solving MIPs as subproblems of the SLP algorithm leads to the “MIP within SLP” variant. It is comparable with an MIP relaxation based outer-approximation algorithm [6]. A third variant (“SLP then MIP”) solves first an NLP relaxation (by SLP), then an MIP relaxation, and

finally an NLP subproblem to obtain a feasible solution to (P) [36]. Also to accommodate nonconvex constraints, in all variants, the hyperplanes obtained from gradient-based linearizations in SLP are allowed to move away from their support point.

FILMINT (Filter-Mixed Integer Optimizer) [37]. This solver has been developed by the research groups of S. Leyffer at the Laboratory for Advanced Numerical Simulations of Argonne National Laboratory and J. T. Linderoth at the Department of Industrial and Systems Engineering of Lehigh University. It provides an AMPL interface.

FILMINT ensures global optimal solutions only for convex MINLPs. It implements a branch-and-bound algorithm that utilizes LPs for bounding [7]. FILMINT is implemented on top of the MIP solver MINTO [59] and the NLP solver FILTERSQP [56].

FMINCONSET [38]. This solver had been developed by I. Solberg at the Department of Engineering Cybernetics of the University of Trondheim (now NTNU). It is available as MATLAB source.

FMINCONSET ensures global optimal solutions for convex MINLPs. It implements a branch-and-bound algorithm utilizing nonlinear relaxations for the bounding step [8]. The NLPs are solved by the MATLAB Optimization Toolbox routine FMINCON.

KNITRO [39]. This solver has been developed by Ziena Optimization, Inc. It is available as standalone binary and as a component in many modeling systems.

KNITRO ensures global optimal solutions for convex MINLPs. MINLPs are solved by branch-and-bound, where both linear or nonlinear problems can be used for the bounding step [7,8].

LAGO (Lagrangian Global Optimizer) [40]. This open-source solver had been developed by the research group of I. Nowak at the Department of Mathematics of Humboldt University, Berlin. It is available in source code from COIN-OR and provides AMPL and GAMS interfaces.

LAGO ensures global optimal solutions for convex MINLPs and nonconvex MIQCPs. It implements a spatial branch-and-bound algorithm utilizing a linear relaxation for the bounding step. The relaxation is obtained by linearizing convex functions, underestimating quadratic nonconvex functions, and approximating nonconvex nonquadratic functions by quadratic ones.

LINDOBB (LINDO Systems Mixed Integer Nonlinear Solver) [41]. This solver has been developed by LINDO Systems, Inc. It is available within the LINDO environment and as a commercial solver within GAMS.

LINDOBB ensures global optimal solutions for convex MINLPs. It was the first commercially available solver implementing a branch-and-bound algorithm utilizing nonlinear relaxations for the bounding step [8]. The NLP relaxations are solved by CONOPT [18,60].

LINDOGLOBAL (LINDO Systems Global Solver) [42,61]. This solver has been developed by LINDO Systems, Inc. It is available within the LINDO environment [41], LINGO [20], *What'sBest!* [62], and as a commercial solver within GAMS.

LINDOGLOBAL ensures global optimal solutions for convex and nonconvex MINLPs. It implements a branch and cut algorithm that utilizes LPs for bounding. Branching is performed for subproblems that are not provably infeasible and where nonconvex constraints are present or the LP relaxation has a fractional solution. Thus, in difference to other spatial branch-and-bound algorithm, branching on a continuous variable especially targets on achieving convexity of (nonlinear) subproblems. LINDOGLOBAL can also handle some nonsmooth or discontinuous functions like $\text{abs}(x)$, $\text{floor}(x)$, and $\text{max}(x, y)$.

MIDACO (Mixed Integer Distributed Ant Colony Optimization) [46,47]. This solver has been developed by M. Schlüter at the Theoretical and Computational Optimization Group of the University of Birmingham. It works as a library with Matlab, C/C++, and

Fortran interfaces and is available from the author on request.

MIDACO can be applied to convex and nonconvex MINLPs. It implements an extended ant colony search method based on an oracle penalty function and can be combined with MISQP as solver for local searches in (P). It targets applications where the problem formulation is unknown ($f(x, y)$ and $g(x, y)$ are black-box functions) or involves critical properties like non-convexities, discontinuities, flat spots, or stochastic distortions. Further, MIDACO can exploit distributed computer architectures by parallelizing function evaluation calls.

MILANO (Mixed-Integer Linear and Nonlinear Optimizer) [48]. This solver is developed by H. Y. Benson at the Department of Decision Sciences of Drexel University. It is still in development and available as MATLAB source.

MILANO ensures global optimal solutions for convex MINLPs. It implements a branch-and-bound algorithm utilizing nonlinear relaxations for the bounding step [8]. The NLPs are solved by LOQO [63], where special emphasis is put on how to warmstart this interior-point solver.

MINLP_BB (Mixed Integer Nonlinear Programming Branch-and-Bound) [8]. This solver had been developed by R. Fletcher and S. Leyffer at the University of Dundee. It provides an AMPL interface and is available for MATLAB via the TOMLAB Optimization Environment [64].

MINLP_BB ensures global optimal solutions for convex MINLPs. It implements a branch-and-bound algorithm utilizing nonlinear relaxations for the bounding step [8]. The NLPs are solved by FILTERSQP.

MISQP (Mixed Integer Sequential Quadratic Programming) [49]. This solver has been developed by the research group of K. Schittkowski at the Department of Computer Science of the University of Bayreuth. It works as a standalone library with a Fortran interface.

MISQP can be applied to convex and non-convex MINLPs, but assumes that the values

of $f(x, y)$ and $g(x, y)$ do not change drastically as a function of y . MISQP implements a modified sequential quadratic programming (SQP) method, where functions are only evaluated at points (x, y) with y integer. It targets applications where the evaluation of $f(x, y)$ or $g(x, y)$ may be expensive.

MOSEK [26]. This solver has been developed by MOSEK ApS. It is available as a standalone binary, has AMPL and MATLAB interfaces, and is distributed as a commercial solver within AIMMS and GAMS.

MOSEK can be applied to convex MIQCPs and to mixed-integer conic programs. It implements a branch-and-bound method that utilizes QCPs or SOC programs for bounding [7].

OQNLP (OptQuest Nonlinear Programming) [18,50]. This solver has been jointly developed by OptTek Systems, Inc. and Optimal Methods, Inc. It is available as a standalone library, for MATLAB via the TOMLAB Optimization Environment, and is distributed as a commercial solver within GAMS.

OQNLP is a heuristic that can be applied to any MINLP. It implements a multistart scatter search algorithm which solves NLP subproblems with fixed discrete variables.

SBB (Simple Branch-and-Bound) [18]. This solver had been developed by ARKI Consulting and Development A/S. It is available as a commercial solver within GAMS.

SBB ensures global optimal solutions for convex MINLPs. It implements a branch-and-bound algorithm utilizing nonlinear relaxations for the bounding step [8]. The NLP relaxations are solved by one (or several) of the NLP solvers available with GAMS. Using the GAMS Branch-Cut-and-Heuristic facility [14], SBB allows the user to implement a model-specific heuristic in the GAMS language.

SCIP (Solving Constraint Integer Programs) [27,28]. This solver has been developed by the Optimization Department at the Zuse Institute, Berlin. For academic institutions, it is available in source code and as standalone binary, and is distributed within GAMS.

SCIP ensures global optimal solutions for convex and nonconvex MIQCPs. It implements a spatial branch-and-bound algorithm utilizing a linear relaxation for the bounding step. The relaxation is obtained by linearizing convex or convexified quadratic functions.

OUTLOOK AND SUMMARY

Combining discrete and nonlinear optimization results in a rich modeling paradigm applicable to many real-world optimization problems. At the same time, mixed integer nonlinear programming represents a theoretically and computationally challenging problem class and hence provides many interesting research opportunities. Software for solving MINLP models facilitates cooperation between research and application and explains the popularity and increased level of activity around MINLP.

While state-of-the-art MIP solvers typically implement advanced automatic reformulation and preprocessing algorithms, such techniques are less commonly available in MINLP solvers, and in a limited form. Therefore, the modeler's choice of problem formulation is still very important when solving an MINLP. However, software for guided automatic model reformulations and relaxations has recently been developed. LOGMIP [45], one of the first systems available, translates an MINLP with disjunctions into a standard MINLP by applying bigM and convex hull reformulations [65]. More recently, frameworks like GAMS/EMP (Extended Mathematical Programming) [66] and ROSE (Reformulation/Optimization Software Engine) [67] provide a growing toolbox for reformulating MINLPs. Other recent activities, like LIBMC [68] and parts of MINOTAUR (Mixed-Integer Nonconvex Optimization Toolbox—Algorithms, Underestimators, Relaxations) [69] focus on (convex) relaxations for (nonconvex) MINLP.

Another important area is the collection and dissemination of MINLP models. Instance collections like MACMINLP [70] and MINLPLIB [71] provide valuable test cases for solver developers. The new Cyber-Infrastructure for MINLP [72] features a

growing library of problems with high level model descriptions, reformulations, and problem instances.

In this article we have given a concise description of the state-of-the-art in MINLP solvers and have established several groupings with respect to various features of the software. We hope that these groupings and the individual descriptions give sufficient information to guide the selection of the best solver for a particular MINLP problem.

MIXING SETS

LAURENCE A. WOLSEY
Center for Operations Research and
Econometrics (CORE) and
Département d'Ingénierie
Mathématique (INMA), Université
Catholique de Louvain
Louvain-la-Neuve, Belgium

A mixing set is a set of the form

$$X^{\text{MIX}} = \{(s, z) \in \mathbb{R}^1 \times \mathbb{Z}^n : \\ s + z_t \geq b_t \text{ for } t = 1, \dots, n\}. \quad (1)$$

Note that the variables s, z are unrestricted in sign, though often in practice, there will be nonnegativity or other bound constraints on the variables. The special case when s is nonnegative will be denoted by X_+^{MIX} .

Mixing sets first arose in the study of lot-sizing problems [1], but were defined explicitly by Günlük and Pochet [2], and have since been generalized in a variety of ways. The majority of applications are to lot-sizing problems, but they arise also in single arc network models, as well as in robust and stochastic integer programming. In addition, attempts are under way to use such sets to generate cutting planes for general mixed integer programs (MIPs).

Below we first describe a few examples in which such sets arise and then we develop the basic theory of such sets: in particular, tight and compact extended formulations whose projection gives the convex hull of the set X^{MIX} ; these can be used to optimize over such sets by linear programming (LP) or network flows; a valid inequality description of $\text{conv}(X^{\text{MIX}})$ and a polynomial separation algorithm that allows one to use these inequalities in a cutting plane algorithm. Next, we present several generalizations of mixing sets and indicate briefly some of the important results concerning the convex hulls of these sets.

SOME APPLICATIONS OF MIXING SETS

Here we present four problems, whose formulations naturally lead to mixing sets.

A Discrete Version of the Newsvendor Problem. Consider a product that can be sold during one season in arbitrary (real-valued) amounts. The demand and future production cost are uncertain. Specifically, it is estimated that with probability p_t , there will be a demand d_t and a production cost of q_t per batch of C units during the coming season, where $t = 1, \dots, n$. The other option is to produce the goods in advance at a unit cost of h . The problem is to minimize the total expected cost given that all demands must be satisfied.

Letting s be the amount produced in advance and z_t the number of batches produced during the season under scenario t , one obtains the MIP,

$$\min \left\{ hs + \sum_{t=1}^n p_t q_t z_t : s + C z_t \geq d_t \right. \\ \left. \text{for } t = 1, \dots, n, s \in \mathbb{R}_+^1, z \in \mathbb{Z}_+^n \right\}.$$

Note that after dividing through by C , the feasible region is a mixing set with nonnegativity constraints on the s and z variables.

Lot-Sizing: The Wagner–Whitin Relaxation. In constant capacity lot-sizing, one is given deterministic (known) demands d_t for periods 1 to n . In each period, one can produce any amount between 0 and the capacity C . The production costs in each period t are p_t per unit plus a fixed setup or order cost q_t if the production is nonzero. In addition, there is per unit end of period storage cost h_t . The problem is to satisfy all the demands at a minimum cost.

Letting x_t be the production in period t , $y_t \in \{0, 1\}$ a variable that must take value 1

if $x_t > 0$ and s_t the stock at the end of period t , one obtains the MIP

$$\min \sum_{t=1}^n p_t x_t + \sum_{t=0}^n h_t s_t + \sum_{t=1}^n q_t y_t \quad (2)$$

$$s_{t-1} + x_t = d_t + s_t \quad \text{for } t = 1, \dots, n \quad (3)$$

$$x_t \leq C y_t \quad \text{for } t = 1, \dots, n \quad (4)$$

$$x \in \mathbb{R}_+^n, s \in \mathbb{R}_+^{n+1}, y \in \{0, 1\}^n. \quad (5)$$

The Wagner–Whitin relaxation is obtained by summing the balance constraints (Eq. 3) for periods k up to t , using Equation (4) to replace x_u by its upper bound $C y_u$ and by replacing s_t by its lower bound of zero. The resulting feasible region is

$$\left\{ (s, y) \in \mathbb{R}_+^{n+1} \times \{0, 1\}^n : s_{k-1} + C \sum_{u=k}^t y_u \geq \sum_{u=k}^t d_u \text{ for } 1 \leq k \leq t \leq n \right\}.$$

For fixed k , taking $\sigma = s_{k-1}/C$, $z_t = \sum_{u=k}^t y_u$, $b_t = (\sum_{u=k}^t d_u)/C$, one obtains

$$\sigma + z_t \geq b_t \text{ for } k \leq t \leq n$$

$$0 \leq z_t - z_{t-1} \leq 1$$

$$\sigma \in \mathbb{R}_+^1, z \in \mathbb{Z}^{n-k+1},$$

which is a mixing set with additional constraints on the integer variables of a very special form. So the Wagner–Whitin relaxation can be viewed as the intersection of n mixing sets with common integer variables.

Probabilistic (Chance-Constrained) Programming. Let $\tilde{\zeta} \in \mathbb{R}_+^d$ be a random vector taking a finite number of discrete values $b^k \in \mathbb{R}_+^d$ with probability p_k for $k = 1, \dots, K$, and suppose that there is a probabilistic constraint that some vector $s \in \mathbb{R}_+^d$ satisfies $s \geq \tilde{\zeta}$ with probability at least $1 - \tau$. Setting $z_k = 0$, if $s \geq b^k$ and $z_k = 1$ otherwise, one

obtains the MIP constraints

$$s_i \geq b_i^k (1 - z_k) \text{ for } k = 1, \dots, K, \\ i = 1, \dots, d \quad (6)$$

$$\sum_{k=1}^K p_k (1 - z_k) \geq 1 - \tau \quad (7)$$

$$s \in \mathbb{R}_+^d, \quad z \in \{0, 1\}^K. \quad (8)$$

With $M \geq \max_{i,k} b_i^k$ an arbitrary large value, constraint (6) can be replaced by

$$s_i + M z_k \geq b_i^k \text{ for } k = 1, \dots, K, i = 1, \dots, d. \quad (9)$$

Now the set defined by Equations (8) and (9) is the intersection of d mixing sets with common 0–1 variables.

Mixing Sets and General MIPs. Suppose that one has a mixed integer set $\{(x, y) \in \mathbb{Z}_+^n \times \mathbb{R}_+^p : Ax + Gy \geq b\}$. One possible relaxation is the set

$$\sum_{j=1}^n \lceil a_{ij} \rceil x_j + \sum_{j=1}^p (\max_i g_{ij}^+) y_j \geq b_i \quad \forall i,$$

where w^+ demotes $\max(w, 0)$. Taking $s = \sum_{j=1}^p (\max_i g_{ij}^+) y_j$, and $z_i = \sum_{j=1}^n \lceil a_{ij} \rceil x_j$, one clearly has a mixing set.

THE PROPERTIES OF MIXING SETS

The Simple Case $n = 2$

When $n = 2$, a simple change of variable $\sigma = s + z_1 - b_1$ allows one to rewrite X^{MIX} as the simple mixed integer set

$$X^{\text{MIP}} = \{(\sigma, y) \in \mathbb{R}_+^1 \times \mathbb{Z}^1 : \sigma + y \geq d\};$$

namely, one substitutes $s = \sigma - z_1 + b_1$ in $s + z_2 \geq b_2$ giving $\sigma + (z_2 - z_1) \geq (b_2 - b_1)$ and then sets $y = z_2 - z_1$ and $d = b_2 - b_1$.

X^{MIP} is a well-studied set. When $d \notin \mathbb{Z}^1$ so that $f_d = d - \lfloor d \rfloor > 0$, addition of the valid inequality

$$s \geq f_d (\lfloor d \rfloor + 1 - y), \quad (10)$$

called the *mixed integer rounding (MIR)* inequality, is sufficient to give a complete description of $\text{conv}(X^{\text{MIP}})$.

The General Case

We consider again the set X^{MIX} with $n \geq 3$ and set $N = \{1, \dots, n\}$. First we present some basic results, an outline of the proofs, along with an example.

Observation 1.

- (i) $\text{conv}(X^{\text{MIX}})$ contains the line $(-1, \mathbf{1})$ and the extreme rays $(1, \mathbf{0})$ and $(0, \mathbf{e}_i)$ for $i \in N$, where $\mathbf{e}_i$ is the i th unit vector, $\mathbf{0} = (0, \dots, 0)$ and $\mathbf{1} = (1, \dots, 1)$.
- (ii) Let $f_t = b_t - \lfloor b_t \rfloor$ for $t \in N$. In an extremal solution of $\text{conv}(X^{\text{MIX}})$, $s \equiv f_t \pmod{1}$ for some t . Specifically, there are the n extremal solutions $(f_t, \lfloor b_1 - f_t \rfloor, \dots, \lfloor b_n - f_t \rfloor)$ for $t \in N$.

Extended Formulations. We say that a polyhedron $Q \subset \mathbb{R}^{n+p}$ is a tight extended formulation for a set $X \subset \mathbb{R}^n$ if $\text{conv}(X) = \text{proj}_x(Q)$, where $\text{proj}_x(Q) \equiv \{x \in \mathbb{R}^n : \exists y \in \mathbb{R}^p \text{ with } (x, y) \in Q\}$.

Theorem 1. *A tight, extended formulation for $\text{conv}(X^{\text{MIX}})$ is given by*

$$\begin{aligned} s - \sum_{t=1}^n f_t \delta_t - \mu &= 0, \\ \mu + \sum_{if_i \geq f_t} \delta_i + z_t &\geq \lfloor b_t \rfloor + 1 \quad \text{for } t \in N \\ \sum_{i=1}^n \delta_i &= 1 \end{aligned}$$

$$\begin{array}{ccccccccccccc}
s & -\mu & -0.9\delta_1 & -0.7\delta_2 & -0.6\delta_3 & & & & & & & & = & 0 \\
& \mu & +\delta_1 & & & & & +z_1 & & & & & \geq & 3 \\
& \mu & +\delta_1 & +\delta_2 & & & & & +z_2 & & & & \geq & 1 \\
& \mu & +\delta_1 & +\delta_2 & +\delta_3 & & & & & +z_3 & & & \geq & -1 \\
& \mu & +\delta_1 & +\delta_2 & +\delta_3 & +\delta_4 & & & & & +z_4 & & \geq & 3 \\
& & \delta_1 & +\delta_2 & +\delta_3 & +\delta_4 & & & & & & & = & 1 \\
s & \in & \mathbb{R}^1, & z & \in & \mathbb{R}^4, & \mu & \in & \mathbb{R}^1, & \delta & \in & \mathbb{R}_+^4.
\end{array}$$

$$s \in \mathbb{R}^1, z \in \mathbb{R}^n, \delta \in \mathbb{R}_+^n, \mu \in \mathbb{R}^1.$$

Proof. Based on (ii) of Observation 1, we take μ to be the integer part of s and $\delta_t = 1$ if $s = f_t \pmod{1}$. Next one observes that after substituting for s , the set

$$= \left\{ (z, \mu, \delta) \in \mathbb{Z}^n \times \mathbb{Z}^1 \times \mathbb{Z}_+^n : \mu + \sum_{i=1}^n f_i \delta_i + z_t \geq b_t \quad \text{for } t \in N, \sum_{t=1}^n \delta_t = 1 \right\}$$

Finally, one observes that the matrix in the z, μ , and δ variables is totally unimodular and the right-hand side vector is an integer, so the integrality of the z, μ , and δ can be dropped.

Example. Consider an instance of X^{MIX} with $n = 4$:

$$\begin{aligned} s + z_1 &\geq 2.9, \\ s + z_2 &\geq 0.7, \\ s + z_3 &\geq -1.4, \\ s + z_4 &\geq 2.0, \\ s &\in \mathbb{R}^1, z \in \mathbb{Z}^4. \end{aligned}$$

The corresponding extended formulation is

Now we show how this inequality can be derived from the extended formulation. We have that

Observation 2 [Nonnegativity of s]. Note that the constraint $s \geq 0$ can be modeled as part of a mixing set by adding the constraints $s + z_{n+1} \geq 0, z_{n+1} = 0$. Now if $T = \{i_1, \dots, i_t, n+1\}$ in Theorem 3, one obtains the additional inequality

$$s \geq \sum_{j=1}^t (f_{i_j} - f_{i_{j+1}})(\lfloor b_{i_j} \rfloor + 1 - z_{i_j}), \quad (17)$$

in which the final term of inequality (16) has disappeared. The terms in these inequalities can be seen as a mixing of the simple MIR inequalities (10). Hence the name mixing sets and mixing inequalities.

It is not difficult to see that the separation problem for the mixing inequalities (16) can be solved in $O(n \log n)$; see Pochet and Wolsey [3].

Observation 3 [Mixing with “ $\leq$ ” Constraints]. The set with “ $\leq$ ” constraints, $X^{\leq} = \{(\sigma, y) \in \mathbb{R}^1 \times \mathbb{Z}^n : \sigma + y_t \leq c_t \text{ for } t \in N\}$ is equivalent to a standard mixing set. It suffices to take $s = -\sigma, z_t = -y_t$, and $b_t = -c_t$ for all t . Note that in this case, it is easy to add an upper bound $s \leq u$ by adding the constraints $\sigma + y_{n+1} \leq u, y_{n+1} = 0$.

NETWORK DUAL GENERALIZATIONS OF MIXING SETS

Here, we consider several extensions of mixing sets and then present a network dual model or bipartite vertex cover model of which the extensions are special cases.

The Double Mixing Set and Bounds on s . This is the set

$$X^{\text{DM}} = \{(s, z) \in \mathbb{R}^1 \times \mathbb{Z}^n : s + z_t \geq b_t \text{ for } t \in N_1, s + z_t \leq c_t \text{ for } t \in N_2\},$$

where $N_1 \cup N_2 = N$. Note that X^{DM} is the intersection of two mixing sets $X^{\text{MIX}}(b)$ and $X^{\leq}(c) = \{(s, z) \in \mathbb{R}^1 \times \mathbb{Z}^n : s + z_t \leq c_t \text{ for } t \in$

$N_2\}$ with the same continuous variable. Conforti *et al.* [4] show

$$\text{conv}(X^{\text{DM}}) = \text{conv}(X^{\text{MIX}}(b)) \cap \text{conv}(X^{\leq}(c)) \\ \bigcap_{(i,j) \in N_1 \times N_2} \{z : z_i - z_j \geq \lceil b_i - c_j \rceil\}.$$

Note that this includes the very special case of a mixing set with both lower and upper bounds on the continuous variable s .

The Continuous Mixing Set. This is the set

$$X^{\text{CM}} = \{(s, r, z) \in \mathbb{R}^1 \times \mathbb{R}_+^n \times \mathbb{Z}^n : \\ s + r_t + z_t \geq b_t \text{ for } t \in N\}.$$

This set was first studied in the context of lot-sizing. The constant capacity Wagner–Whitin relaxation of the problem with backlogging is the set

$$X^{\text{WW-CC-B}} \\ = \left\{ (s, r, y) \in \mathbb{R}_+^1 \times \mathbb{R}_+^n \times \{0, 1\}^n : s_{k-1} \right. \\ \left. + \sum_{u=k}^t y_u + r_t \geq \sum_{u=1}^t d_u \text{ for } 1 \leq k \leq t \leq n \right\}.$$

Fixing k and setting $x_t = \sum_{u=k}^t y_u$, one sees that this set is an intersection of n continuous mixing sets.

A first extended formulation for $\text{conv}(X^{\text{CM}})$ with $O(n^2)$ variables and constraints was given in Ref. 5. Later Van Vyve in Ref. 6 presented an extended formulation with $O(n)$ variables and $O(n^2)$ constraints. He also showed that every facet-defining inequality is a “cycle” inequality. Consider the complete directed graph D on n nodes, and let C be a directed cycle in D . Let γ_C denote the number of arcs $(i, j) \in C$ such that $i > j$. Then the cycle inequality is the following inequality

$$\gamma_C s + \sum_{i \in V(C)} r_i + \sum_{(i,j) \in C: i < j} (f_i - f_j)(z_i - \lfloor b_i \rfloor) \\ + \sum_{(i,j) \in C: i > j} (1 + f_i - f_j)(z_i - \lfloor b_i \rfloor) \geq \sum_{(i,j) \in C: i > j} f_j.$$

He also showed that the separation algorithm could be solved by finding a negative cost cycle in an n -node weighted directed graph.

The Mixing Set with Flows. This is the set

$$X^{\text{MF}} = \{(s, z, x) \in \mathbb{R}^1 \times \mathbb{R}_+^n \times \mathbb{Z}^n : \\ s + z_t \geq b_t, z_t \leq x_t \text{ for } t \in N\}.$$

This set can be used to model a slightly more general version of the discrete newsvendor problem described above in which one can produce an amount z_t that is not a multiple of the batch size C , but one then pays both a per unit cost and a fixed batch cost.

Consider the family of n mixing sets

$$X_k^{\text{MF}} = \{(\sigma_k, x_{k+1}, \dots, x_n) \in \mathbb{R}_+^1 \times \mathbb{Z}_+^{n-k} : \\ \sigma_k + x_{k+t} \geq b_t - b_k \text{ for } t = k+1, \dots, n\}$$

for $k = 0, \dots, n-1$, where $x_0 = b_0 = 0$.

Conforti *et al.* showed in Ref. 7 that

$$\text{conv}(X^{\text{MF}}) = \text{proj}_{s,x,z}(\cap_{k=0}^{n-1} \text{conv}(X_k^{\text{MF}})) \cap \{(\sigma, x) : \\ \sigma_k = s + x_k - b_k \forall k\} \cap \{(z, x) : \\ z_t \leq x_t \text{ for } t \in N\}.$$

The Continuous Mixing Set with Flows. Combining the previous two models, one obtains the continuous mixing set with flows

$$X^{\text{CMF}} = \{(s, r, z, x) \in \mathbb{R}^1 \times \mathbb{R}_+^n \times \mathbb{R}_+^n \times \mathbb{Z}^n : \\ s + r_t + z_t \geq b_t, z_t \leq x_t \text{ for } t \in N\}.$$

An extended formulation is given in Ref. 8. Recently, in Ref. 4, Conforti *et al.* consider the family of sets

$$X_Q^{\text{CMF}} = \{(s, r, z, x) \in \mathbb{R}^1 \times \mathbb{R}_+^n \times \mathbb{R}_+^n \times \mathbb{Z}^n : \\ s + r_t + z_t \geq b_t \text{ for } t \in N, z_t \geq 0 \\ \text{for } t \in Q, z_t \leq x_t \text{ for } t \in N \setminus Q\},$$

where $Q \subseteq N$.

They show that

$$\text{conv}(X^{\text{CMF}}) = \bigcap_{Q \subseteq N} \text{conv}(X_Q^{\text{CMF}}),$$

and show that the inequalities needed to describe $\text{conv}(X_Q^{\text{CMF}})$ closely resemble the cycle inequalities describing the continuous mixing set, and the separation problem is again a negative cycle problem.

The Enlarged Mixing Set. Given additional values u_t for $t \in N$, this is the set

$$X^{\text{EM}} = \{(s, v, z) \in \mathbb{R}_+^1 \times \mathbb{R}_+^n \times \mathbb{Z}^n : \\ s + \sum_{i=1}^t v_i + z_t \geq b_t, v_t \leq u_t \text{ for } t \in N\}.$$

Such sets can be used to model lot-sizing problems with sales in which the demand in each period is a fixed amount d_t plus a variable amount v_t lying between 0 and u_t [9]. Given $Q \subseteq N$, consider the set

$$X_Q^{\text{EM}} = \{(s + \sum_{i \in N \setminus Q} v_i, z) \in \mathbb{R}_+^1 \times \mathbb{Z}^n : \\ s + \sum_{i \in N \setminus Q} v_i + z_t \geq b_t - \sum_{i \in Q: i \leq t} u_i \text{ for } t \in N\}.$$

This is again a mixing set and it is shown in Ref. 10 that

$$\text{conv}(X^{\text{EM}}) = \bigcap_{Q \subseteq N} \text{conv}(X_Q^{\text{EM}}) \cap \{v \in \mathbb{R}_+^n : v \leq u\}.$$

The optimization problem over such sets is polynomially solvable because the objective function allows one to restrict oneself to the intersection of just $n+1$ of the 2^n mixing sets. However, no polynomial time combinatorial separation algorithm is known.

The Network Dual and Bipartite Vertex Cover Sets

Given a directed graph $D = (V, A)$, $b \in \mathbb{Q}^{|A|}$ and a partition (I, L) of V , the network dual set is the set

$$X^{\text{ND}} = \{x \in \mathbb{R}^{|V|} : x_i - x_j \geq b_{ij} \\ \text{for } (i, j) \in A, x_i \in \mathbb{Z}^1 \text{ for } i \in I, \}$$

introduced in Ref. 11. Here I is the set of indices of the integer variables and L that of the continuous variables. It is not difficult to see that most of the sets described above can be rewritten as network dual sets. As

an example, for the continuous mixing set, it suffices to make the change of variables $\rho_t = s + r_t$ and $y_t = -x_t$. Then $s + r_t + x_t \geq b_t$ becomes $\rho_t - y_t \geq b_t$, and $r_t \geq 0$ becomes $\rho_t - s \geq 0$.

As for the mixing set, a crucial object is the set of fractional values encountered by the continuous variables $x_i, i \in L$ in extremal solutions. Suppose that the K possible values are $1 > f_1 \geq \dots \geq f_K \geq 0$. As for the extended μ formulation of $\text{conv}(X^{\text{MIX}})$, we define the μ variables as follows:

$$\begin{aligned}\mu_k^i &= \lfloor x_i \rfloor \text{ if } x_i < \lfloor x_i \rfloor + f_k \text{ and} \\ \mu_k^i &= \lfloor x_i \rfloor + 1 \text{ if } x_i \geq \lfloor x_i \rfloor + f_k.\end{aligned}$$

Now one obtains an extended formulation by reformulating each constraint $x_i - x_j \geq b_{ij}$ separately

$$x_i = \sum_{\ell=0}^K \mu_\ell^i (f_\ell - f_{\ell+1}) \quad i \in V \quad (18)$$

$$\mu_K^i - \mu_0^i = 1, \quad i \in V \quad (19)$$

$$\mu_k^i - \mu_{k-1}^i \geq 0, \quad 1 \leq k \leq K, \quad i \in V \quad (20)$$

$$\mu_k^i - \mu_{q_k^{ij}}^j \geq \beta_k^{ij} \quad 1 \leq k \leq K, (i, j) \in A \quad (21)$$

$$x_i = \mu_k^i \text{ for } k = 0, 1, \dots, K, i \in I, \quad (22)$$

where $f_{ij} = b_{ij} - \lfloor b_{ij} \rfloor$, and q_k^{ij} and β_k^{ij} are calculated as follows:

$$\begin{aligned}\text{if } f_{ij} - f_{k+1} > 0, \text{ then } q_k^{ij} &= \max\{t : f_t + f_{ij} - f_{k+1} > 1\} \text{ and } \beta_k^{ij} = \lfloor b_{ij} \rfloor + 1, \\ \text{if } f_{ij} - f_{k+1} \leq 0, \text{ then } q_k^{ij} &= \max\{t : f_t + f_{ij} - f_{k+1} > 0\} \text{ and } \beta_k^{ij} = \lfloor b_{ij} \rfloor.\end{aligned}$$

Observing again that the corresponding matrix is TU, one has the following theorem.

Theorem 4. *The polyhedron (18)–(22) is an extended formulation for $\text{conv}(X^{\text{ND}})$.*

Note that even after replacement of μ_k^i by x_i for all $i \in I$, the resulting system still has $K|L|$ additional variables and $K|\tilde{A}|$ constraints of the form (21), where $\tilde{A} = \{(i, j) \in A : i, j \in L\}$.

Corollary 1. *If K is polynomial in the input size of $D = (V, A)$ and b , linear programming over the extended formulation provides a polynomial algorithm for optimization over X^{ND} .*

It is natural to ask when K is of polynomial size. For most of the lot-sizing examples and for the continuous mixing set with flows, it can be shown that $K = O(n^2)$. More generally, it is the structure of the “continuous arc” subgraph $\tilde{D} = (V, \tilde{A})$ that is important. In fact, when the underlying undirected graph of D is acyclic, one can show that K is of polynomial size.

We now consider a second model. Given a bipartite graph $G = (U, V, E)$, $b_e \in \mathbb{Q}^{|E|}$ and a set $I \subset U_1 \cup U_2$, the (mixed integer) bipartite vertex cover set is the set

$$\begin{aligned}X^{\text{BVC}} &= \{x \in \mathbb{R}^{U \cup V} : x_i + x_j \geq b_e \\ &\text{for } e \in E, x_i \in \mathbb{Z}^1 i \in I\}.\end{aligned}$$

Conforti *et al.* [12] first examined the case in which the b_e is an half-integer and gave a complete description of the facet-defining inequalities of $\text{conv}(X^{\text{BVC}})$. In Ref. 4, the network dual and bipartite vertex cover models are shown to be equivalent, and the structure of the facets is studied when the corresponding “continuous edge” subgraph is a tree. It is easy to see that X^{BVC} can be transformed into X^{ND} just by taking $y_j = -x_j$ for all $j \in U_2$. To go in the other direction, one can construct a bipartite graph $G = (V, \bar{V}, E)$, where $\bar{V}$ is a copy of V representing the variables $\bar{x}_i = -x_i$ for $i \in V$, $E = \{(i, j) \in A\} \cup \{(i, i) : i \in V\}$ and $b_e = b_{ij}$ for $(i, j) \in A$, and for (i, i) the constraints are $x_i + \bar{x}_i \geq 0$. Now the face of $X^{\text{BVC}} \cap \{(x, \bar{x}) : x_i + \bar{x}_i = 0 \text{ } i \in V\}$ gives X^{ND} .

Further Generalizations of Mixing Sets

The Divisible Capacity Mixing Set. This is the set

$$\begin{aligned}X^{\text{DCM}} &= \{(s, z) \in \mathbb{R}^1 \times \mathbb{Z}^n : s + C_t z_t \geq b_t \text{ for } t \in N\},\end{aligned}$$

where $C_1|C_2|\dots|C_n$. This set was first studied by Van Vyve [13] as an abstraction of a lot-sizing problem with constant upper and lower

bounds on production. In Ref. 14, an extended formulation, inequalities, and a separation algorithm are given for the special case in which the C_i only take two distinct values and all the variables are nonnegative. Later, de Farias and Zhao [15] presented an extended formulation for $\text{conv}(X^{\text{DCM}})$ and an alternative formulation was produced by Di Summa [16] which could also be extended to deal with bounds on the s variable. A very different formulation is given in Ref. 17. Very recently, Conforti and Zambelli [18] have shown how, by a unimodular transformation, the problem becomes simple to solve and also leads to an extended formulation that is a shortest path problem. However, this approach does not allow one to handle bounds on any of the variables.

The Generalized Mixing Set. When the C_i are not divisible, one obtains the generalized mixing set

$$X^{\text{GMIX}} = \{(s, z) \in \mathbb{R}^1 \times \mathbb{Z}^n : s + C_t z_t \geq b_t \text{ for } t \in N\}.$$

This problem has been shown to be *NP*-hard by Eisenbrand and Rothvoss [19], based on a reduction from a problem of diophantine approximation.

The Divisible Capacity Discrete Lot-Sizing Set.

$$X^{\text{DCLS}} = \left\{ (s_0, y) \in \mathbb{R}_+^1 \times \{0, 1\}^{Kn} : \right. \\ \left. s_0 + \sum_{u=1}^t \sum_{k=1}^K C_k y_u^k \geq b_t \text{ for } t \in N \right\}.$$

Results for this model would provide interesting relaxations for lot-sizing problems with different production alternatives. When $K = 1$, this is just the discrete version of the Wagner–Whitin lot-sizing set presented in the section titled “The Properties of Mixing Sets.” For $K = 2$, it is closely related to the continuous mixing set, but nothing is known for $K \geq 3$.

REMARKS AND OPEN QUESTIONS

Related to the attempt to construct mixing sets as relaxations of general mixed integer sets, Dash and Günlük [20] define the mixing closure of a set and show that it is polyhedral. They also consider the more standard split rank, and show that the mixing inequality (16) has rank at most $n - 1$. Dey [21], on the other hand, has demonstrated a lower bound on the split rank of $\log n$. Another attempt to use mixing sets to obtain valid inequalities for general MIPs is explored by Dey and Wolsey [22], based on lifting a mixing inequality into a valid inequality for any two (or more) row-basic LP tables. The computational effectiveness of using mixing sets and inequalities for general mixed integer sets is still to be investigated.

One significant open question is the complexity of the optimization problem over network dual or bipartite vertex cover sets, even when restricted to certain classes of digraphs. Another concerns the complete structure of the facet-defining inequalities in the case where the underlying “continuous arc” subgraph is a tree.

There are also questions concerning algorithms for the optimization and separation problems for the mixing set and its generalizations. For the optimization problem, one knows that the dual of the extended formulation is a network flow problem, so one might hope to find specialized network flow algorithms.

More generally, it is natural to ask whether there are other simple mixed integer sets with such a rich structure.

INTRODUCTION

A forecasting model is a mathematical representation of the forecasted process. It is important to distinguish a model from formula or forecasting method: A method is just a rule or formula for computing a forecast. The latter may or may not depend on a model. The goal of the article is to introduce the most widely used forecasting model to the reader, provide a classification of existing models, and offer a guideline for further study of this area.

The forecasting is based on the data from previous time points, that is, the values of one or more additional time series variables, called *predictor* or *explanatory variables*. These variables are used by the model to forecast the output. The selection (or identification) of the model is performed based on a partial understanding of the forecasting phenomenon and/or scientific intuition. Then, when selected, the goal is to tune the model parameters to fit the data in a certain sense. Lastly, it is important to ensure that the model adequately describes the process using statistical validation techniques.

The section titled “Linear Models” provides an introduction to linear models, that is, models which are described by linear equations. We start from the Autoregressive Integrated Moving Average (ARIMA). The autoregressive part (AR) determines the forecast based on the previous time series values (regressors). The moving average (MA)

term determines the noise of the model. The Box–Jenkins family of models is an example of integrated AR and MA models. State-space models provide forecasting based on the input and an internal state of the model, which is switched over time according to certain transition rules. Bayesian forecasting is done based on some prior knowledge of the model that is iteratively updated when new data are received.

The nonlinear models use nonlinear functions explaining the underlying phenomena. In many cases, they extend corresponding linear models allowing the forecasts to describe a wider set of processes. Nonlinearity does however provide extra computational and theoretical challenges. The section titled “Nonlinear Models,” introduces some popular models of the nonlinear family such as nonlinear dynamic regression models, nonlinear MA models, nonlinear autoregressive (NLAR) models, smooth transition autoregressive (STAR) models, and Markov-switching models.

LINEAR MODELS

In this section, we will consider the linear models for producing forecasts of time series data. Even though the time series contains some nonlinearities, linear forecasts can be considered as a good benchmark or can compete with nonlinear ones [1]. As there is a vast array of linear models, we will focus on the extensive class of ARIMA, state-space, and Bayesian-based forecasting models.

ARIMA Models

The ARIMA class of models is an important forecasting tool, and forms the basis for many fundamental ideas in time series analysis. The ARIMA approach to time series forecasting dominated the statistical literature in the 1970s and early 1980s, and attracted much attention in control engineering. The studies on the characteristics and performance of these models are presented in Refs 2–5.

Autoregressive Processes. The most popular approach for modeling univariate time series is the AR model. A process y_t is said to be an AR process if

$$y_t = \phi_1 y_{t-1} + \phi_2 y_{t-2} + \cdots + \phi_p y_{t-p} + z_1. \quad (1)$$

where ϕ are the parameters of the model and z_1 is a random variable. The value of p designates the order of the AR model. An AR model is simply a linear regression of the current value of the series against one or more previous values. The simplest AR process is the first-order case denoted by AR(1), and is given as follows:

$$y_t = \phi_1 y_{t-1} + z_t. \quad (2)$$

If $\phi_1 = 1$, we obtain the nonstationary, random walk model. However, if $\phi_1 < 1$, it can be shown that the process is stationary, with autocorrelation function (ac.f.) given by $\rho_k = \phi^k$ for $k = 0, 1, 2, \dots$

Moving Average Processes. Another common approach for modeling univariate time series models is the MA model. The process $\{y_t\}$ is said to be an MA process of order q , if it has the following structure:

$$y_t = z_t + \theta_1 z_{t-1} + \cdots + \theta_q z_{t-q}. \quad (3)$$

where $\theta_1 \dots \theta_q$ are the parameters of the model and the $z_t, z_{t-1}, \dots$ are the error terms.

Conceptually, the MA model is a linear regression of the current value of the series against the white noise (or random shocks) of one or more of the previous values of the series. The random shocks at each point $\{z_t\}$ are assumed to come from the same distribution, typically a normal distribution. Unlike AR models, the error terms are not observable and therefore, fitting the model is a more challenging task. Normally, iterative nonlinear fitting procedures are used instead of least-squares to restore the parameters [6]. The simplest example of an MA process is the first-order case, denoted as MA(1), given by

$$y_t = z_t + \theta_1 z_{t-1}. \quad (4)$$

It can be shown that this process is stationary for all values of θ , with an ac.f. given by

$$\rho_k = \begin{cases} 1, & k = 0, \\ \theta/(1 + \theta^2), & k = 1, \\ 0, & k > 1. \end{cases} \quad (5)$$

Box–Jenkins Models. Two statisticians Box and Jenkins proposed to combine AR and MA models, which resulted in the procedure that is known today as *Box–Jenkins forecasting* [2,7]. The notation ARMA(p, q) refers to the model with p AR terms and q MA terms:

$$y_t = c + z_t + \sum_{i=1}^p \phi_i y_{t-i} + \sum_{i=1}^q \theta_i z_{t-i}, \quad (6)$$

where c is a constant and z_t is white noise.

Accurate forecasting depends on finding a suitable model for a given time series. For this, the Box–Jenkins approach uses an iterative three-stage procedure:

1. *Model Identification and Plausible Model Selection.* This ensures that the variables are stationary and decide which (if any) AR or MA component should be used in the model.
2. *Fitting the Model.* One uses econometric computation algorithms to obtain coefficients which best fit the selected ARIMA model. The most widely used methods are maximum likelihood estimation or nonlinear least-squares estimation.
3. *Checking.* One tests whether the estimated model fulfils the specifications of a stationary univariate process. If it is necessary, a better model is built.

The most general Box–Jenkins model includes difference operators to cope with nonstationarity, AR terms, MA terms, seasonal difference operators, seasonal AR terms, and seasonal MA terms.

State-Space Model

The state-space model is defined by two equations: an observation equation that describes how the hidden state or latent process is observed and a state equation that defines the evolution of the process through time.

In state-space, the signal at time t is taken to be a linear combination of a set of variables (state variables), which constitute the state vector at time t . Denoting the number of state variables by m , and the $(m \times 1)$ state vector by θ_t , we can write

$$y_t = h_t^T \theta_t + n_t, \quad (7)$$

where h_t is assumed to be a known $(m \times 1)$ vector, and n_t denotes the observation error, assumed to have a zero mean.

The set of state variables may be defined as the smallest possible subset of system variables that can represent the future behavior of the system and is completely determined by the present values of the state variables. Thus, the future is linearly independent of past values. This means that the state vector possesses a Markovian property: the latest value is all that is needed for making predictions.

It may not be possible to directly observe all (or even any) of the elements of the state vector, θ_t , but it may be reasonable to make assumptions about how the state vector changes over time. A key assumption of the linear state-space model is that the state vector evolves according to the equation

$$\theta_t = G_t \theta_{t-1} + \omega_t, \quad (8)$$

where the $(m \times m)$ matrix G_t is assumed to be known and ω_t denotes an m -vector of disturbance having a zero mean. The general form of the univariate state-space model is composed of two equations (Eqs 7 and 8). Equation (7) is known as the *observation* (or *measurement*) equation, while Equation (8) is called the *transition* (or *system*) equation.

Point forecasts can readily be obtained for the general state-space model by applying the *Kalman filter* [8]. This procedure requires knowledge of the most recent state vector and

the exact value of the current state vector

$$\hat{y}_N(h) = h_{N+h}^T \theta_{N+h}, \quad (9)$$

where h_{N+h} is assumed to be known, and $\theta_{N+h} = G_{N+h} G_{N+h-1} \dots G_{N+1} \theta_N$, if future values of G are also known. In practice, the exact value of θ_N is not known and has to be estimated from data up to time N .

Equation (9) is then replaced by an estimate $\hat{y}_N(h) = h_{N+h}^T \hat{\theta}_{N+h}$. In the special case, where h_t and G_t are known constant functions, say h and G , then the forecast is given by

$$\hat{y}_N(h) = h^T G^h \hat{\theta}_N. \quad (10)$$

Assuming the structure of the model is known, the forecasts depend on obtaining strong estimates of the current state vector θ_N . A basic property of state-space models is that the latter quantity can easily be obtained by updating the formula of the Kalman filter as each new observation becomes available [6]. The Kalman filter will also give estimates of the variance–covariance matrix of $\hat{\theta}$ to indicate the likely size of estimation errors.

The Kalman filter has two distinct phases: *prediction* and *update*. The prediction phase uses the state estimate from the previous time step ($t-1$) to get the forecast θ_t at the current time step. If we denote the resulting predicted state by $\hat{\theta}_{t|t-1}$, then according to Equation (8), it can be calculated as follows:

$$\hat{\theta}_{t|t-1} = G_t \hat{\theta}_{t-1}. \quad (11)$$

It can be shown that the variance–covariance matrix of this estimate is given by

$$P_{t|t-1} = G_t P_{t-1} G_t^T + W_t, \quad (12)$$

where W_t is the known variance–covariance matrix.

In the update phase, when the new observation y_t at the current time step t becomes available, the prediction is refined and a new, presumably more accurate, state estimate is obtained again for the current time step using the following equation:

$$\hat{\theta}_t = \hat{\theta}_{t|t-1} + K_t e_t \quad (13)$$

and

$$P_t = P_{t|t-1} - K_t h_t^T P_{t|t-1}, \quad (14)$$

where

$$e_t = y_t - h_t^T \hat{\theta}_{t|t-1} \quad (15)$$

is the prediction error at time t , and

$$K_t = \frac{P_{t|t-1} h_t}{h_t^T P_{t|t-1} h_t + \sigma_n^2} \quad (16)$$

is called the *Kalman gain matrix*.

Bayesian Forecasting

The Bayesian forecasting procedure is based on the dynamic linear model. This model is based on the idea of Kalman filtering and is useful to predict time series data if the generating process changes over time. In an AR model, it would be necessary to make new identifications and estimations of the model if something changed, whereas in a dynamic linear model these changes are included automatically.

Although it looks like a state-space model, the forecasts are based on a Bayesian rationale, which involves updating prior estimates of model parameters to get posterior estimates. The set of recurrence relationships is particularly useful for short series, where the presence of some prior information [6,9] has been confirmed.

Bayesian methods of forecasting are based on two simple principles:

1. *Explicit Formulation.* Formal probability statements as (i) future event of interest and (ii) relevant events observed at the same time as the decisions are used to express all assumptions.
2. *Relevant Conditioning.* The distribution of future events is conditional upon observed relevant events which have to be used.

In the Bayesian method, the information about point estimate θ is contained not in a single point estimate but in the posterior density $p(\theta|y)$, and so prediction is

correspondingly based on averaging $p(z|y, \theta)$ over this posterior density [10]. In general $p(z|y, \theta) = p(z|\theta)$, that is, predictions do not depend on the observations when θ is given. Therefore, in case of discrete θ , the predicted or replicated data z given the observed data y is equal

$$p(z|y) = \sum_{\theta} p(z|\theta) p(\theta|y) \quad (17)$$

and for continuous θ case, the predicted data z is an integral over the product $p(z|\theta) p(\theta|y)$. In the sampling approach, with iterations $t = B + 1, \dots, B + T$ after convergence, this involves iteration-specific samples of $z(t)$ from the same likelihood form used for $p(y|\theta)$, given the sampled value $\theta(t)$.

NONLINEAR MODELS

In practice, many stationary phenomena can be described or at least approximated by stationary linear time series models. However, many nonlinear phenomena cannot be described adequately by linear time series models, unless superfluous parameters are involved [11]. In recent years, the interest in nonlinear time series models has steadily increased, especially in the field of empirical economics. This has yielded a huge amount of nonlinear models, and it is not possible to present all of them in this section. Here, we introduce a number of well-known nonlinear forecasting models excluding nonparametric ones and discuss their properties.

There are two possibilities to produce forecasts from nonlinear models. Sometimes it is possible to use analytical formulas as in linear models. In many other cases, forecasts more than one period ahead have to be generated numerically. We focus on the nonlinear MA and AR models, the Markov-switching or hidden Markov regression model, and a few others.

Nonlinear Dynamic Regression Model

A general nonlinear dynamic model with a noise component can be defined as follows:

$$y_t = f(z_t; \theta) + \varepsilon_t, \quad (18)$$

where $z_t = (w_t', x_t')$ is a vector of explanatory variables, $w_t = (1, y_{t-1}, \dots, y_{t-p})'$, and the vector of strongly exogenous variables $x_t = (x_{1t}, \dots, x_{kt})'$. Furthermore, $\varepsilon_t \sim \text{iid}(0, \sigma^2)$. There are many popular special cases of this model applied in forecasting; these can be found in Ref. 12.

Nonlinear Moving Average Models

A general nonlinear MA model of order q may be defined as follows:

$$y_t = f(\varepsilon_{t-1}, \varepsilon_{t-2}, \dots, \varepsilon_{t-q}, \theta) + \varepsilon_t, \quad (19)$$

where $\{\varepsilon_t\} \sim \text{iid}(0, \sigma^2)$. The common characteristic of such models is that if the model is invertible, forecasts from it for more than q steps ahead equal the unconditional mean of y_t . In case of unknown invertibility conditions, the models cannot be used for forecasting. When nonlinear MA models are linear in parameters, forecasting is easy in the sense that no numerical techniques are required for the several steps ahead forecasts. Wecker [13] proposed the asymmetric moving average (asMA) model, which has the following form:

$$y_t = \mu + \sum_{j=1}^q \theta_j \varepsilon_{t-j} + \sum_{j=1}^q \psi_j I(\varepsilon_{t-j} > 0) \varepsilon_{t-j} + \varepsilon_t, \quad (20)$$

where $I(\varepsilon_{t-j} > 0) = 1$, when $\varepsilon_{t-j} > 0$ and zero otherwise, and $\{\varepsilon_t\} \sim \text{iid}(0, \sigma^2)$. This model has the property that the effects of a positive shock and a negative shock of the same sizes on y_t are not symmetric when $\psi \neq 0$ for at least one $j, j = 1, \dots, q$.

Nonlinear Autoregressive Models

The NLAR model is a natural extension of the linear AR model. It attracted considerable interest in the 1990s. More details on this model can be found in Refs 14–16.

The general NLAR model of order p has the following form:

$$y_t = k(y_{t-1}, y_{t-2}, \dots, y_{t-p}; \theta) + \varepsilon_t, \quad (21)$$

where $\{\varepsilon_t\}$ is a sequence of $\text{iid}(0, \sigma^2)$ variables.

Guo *et al.* have introduced a multistep prediction procedure for NLAR models based on empirical distribution in Ref. 1. Kapetanios has investigated the features of AR processes including the long memory behavior [17]. The relationship between the stationary marginal tail and the innovation's tail probability has been studied in Ref. 18. The research on the stability of NLAR models are presented in Ref. 19.

Switching Regression and Threshold Autoregressive Model. The standard switching regression (SR) model is piecewise linear and is defined as follows:

$$y_t = \sum_{j=1}^{r+1} (\phi_j' z_t + \varepsilon_{jt}) I(c_{j-1} < s_t \leq c_j), \quad (22)$$

where $z_t = (w_t', x_t')$ is defined as before, s_t is a switching variable, c_j are threshold parameters, and $c_0 = -\infty, c_{r+1} = +\infty$. In addition, $\{\varepsilon_{jt}\} \sim \text{iid}(0, \sigma_j^2)$ and $j = 1, \dots, r$. It can be noticed that Equation (22) is a piecewise linear model with generally unknown switch-points.

The threshold autoregressive (TAR) model was introduced by Tong [20]. The first-order TAR has the following form:

$$x_t = \sum_{j=1}^{r+1} (\phi_j' z_t + \varepsilon_{jt}) I(c_{j-1} < s_t \leq c_j). \quad (23)$$

When x_t is absent and $s_t = y_{t-d}, d > 0$, the Equation (22) becomes the self-exciting threshold autoregressive (SETAR) model. The class of SETAR models has been widely employed and their forecasting performance and statistical characteristics have been examined in Refs 21 and 22. This class is typically applied as an extension of AR models allowing a higher degree of flexibility in model parameters through regime-switching behavior [23]. The SETAR model is a useful tool for predicting future values, assuming that when the behavior of the series changes, the series enters a different regime.

The simple first-order SETAR model has the following expression:

$$y_t = \phi_{11} y_{t-1} I(y_{t-1} \leq c) + \phi_{12} y_{t-1} I(y_{t-1} > c) + \varepsilon_t, \quad (24)$$

where $I(A)$ is an indicator function: $I(A) = 1$ when event A occurs and zero otherwise. The necessary and sufficient condition for this SETAR process to be geometrically ergodic is $\phi_{11} < 1$, $\phi_{12} < 1$, and $\phi_{11}\phi_{12} < 1$. Normally, for higher-order models only sufficient conditions exist and these conditions are quite restrictive.

Suppose we have data up to time N and that y_N happens to be larger than threshold c . It is obvious from the model that $\hat{y}_N(h) = E[y_{N+h} | \text{data to time } N] = \phi_{12} y_N$, and so the one-step-ahead forecast is easy to find.

However forecasting two and more steps ahead becomes more complicated, since it depends on whether the next observation exceeds the threshold. Thus, we need to account for the expectation of future errors that are affected by the threshold. Practitioners use a “deterministic” rule, in which future errors are assumed to have a zero value. In case of the above model, if the observation is smaller than the threshold c , we take

$$\hat{y}_N(2) = \phi_{11} \hat{y}_N(1) = \phi_{11} \phi_{12} y_N. \quad (25)$$

However, this is only an approximation to the true conditional expectation namely, $E[y_{N+2} | \text{data to time } N]$. It is possible to write the conditional expectation analytically for a finite fixed delay d , but in general the forecast cannot be found analytically.

Smooth Transition Autoregressive Model

The STAR model was developed and presented by Chan and Tong [24]. The survey on STAR model and its modification can be found in Refs 25 and 26. These models are usually applied to allow a higher degree of flexibility in model parameters through a smooth transition.

A k -dimensional 2-regime STAR(1) can be defined as

$$y_t = (\phi_{1,0} + \phi_{1,1} y_{t-1} + \cdots + \phi_{1,p} y_{t-p} (1 - G(s_t; \gamma, c)) + (\phi_{2,0} + \phi_{2,1} y_{t-1} + \cdots + \phi_{2,p} y_{t-p} G(s_t; \gamma, c) + \varepsilon_t), \quad (26)$$

where $y_t = (y_{1t}, \dots, y_{kt})'$ is a $k \times 1$ vector time series, $\phi_{i,0}$, $i = 1, 2$ are $k \times 1$ vectors, $\phi_{i,j}$, $i = 1, 2, j = 1, \dots, p$ are $k \times k$ matrices.

There are several extensions of the STAR model, for example, STAR model with exponential or logistic transition function (Exponential STAR or Logistic STAR), models allowing for multiple regimes (MRSTAR), time-varying properties in conjunction with regime-switching behavior (TVSTAR), and modeling several times series jointly. More details on these models can be found in Refs 25 and 27–29.

Markov-Switching Model

Another way of addressing the nonlinear nature of the forecasted process is the Markov-switching model. The Markov process, when embedded in the model, allows for switching between regimes over time.

It is said that a stochastic process satisfies the Markovian property, if the probability of being in a particular state depends on the state directly before and not on older states. Transitions between states happen according to fixed probabilities.

The regime-switching model has several sets of parameters. Each set corresponds to the regime of the system (the state of an embedded Markov process) at a certain moment of time. The Markov-switching model can be defined by the following equation:

$$y_t = \sum_{j=1}^r \alpha'_j z_t I(s_t = j) + \varepsilon_t, \quad (27)$$

where $\{s_t\}$ follows a Markov chain. If the order equals one, the conditional probability of the event $s_t = i$ given s_{t-k} , $k = 1, 2, \dots$, is

only dependent on s_{t-1} and equals

$$Pr s_t = i | s_{t-1} = j = p_{ij}, i, j = 1, \dots, r, \quad (28)$$

such that $\sum_i i = 1' p_{ij} = 1$. The transition probabilities p_{ij} are unknown and have to be estimated from the data. The error process ε_t is often assumed to not be dependent on the “regime” or the value of s_t , but the model may be generalized to incorporate that possibility.

Markov-switching models can be applied when the data can be conveniently thought of as having been generated by a model with different regimes such that the regime changes do not have an observable or quantifiable cause [30]. They may also be used when data on the switching variable is not available and no suitable proxy can be found. This is one of the reasons why Markov-switching models have been fitted to interest rate series, where changes in monetary policy have been a motivation for adopting this approach. Modeling asymmetries in macroeconomic series has, as in the case of SETAR and STAR models, been another area of application.

CONCLUSIONS

Model-based forecasting is the identification of the model behind the process of interest, fitting the parameters of the model according to the training set, and performing statistical test validating the selected model with respect to the test set.

This article provides a brief introduction to several popular forecasting models representing a large family of forecasting approaches. We refer the reader to the exhaustive guidelines to the models presented here, as well as many others in Refs 6, 9, and 31–33.

MODELING AND FORECASTING BY MANIFOLD LEARNING

XUELEI (SHERRY) NI
Department of Mathematics
and Statistics, Kennesaw
State University,
Northwest Kennesaw,
Georgia

It is now common to encounter data sets with hundreds or thousands of attributes, instead of the handful ones one had a few decades ago. A key step to the success of data analysis is to model the data with fewer attributes, while capturing the main characteristics after the reduction of dimensionality. Manifold-based learning is a new and promising approach in nonparametric dimension reduction. In this article, we review state-of-the-art developments in manifold learning, as well as its interesting application in forecasting.

We start with recalling the definition of a manifold. In mathematics, a manifold is a topological space that is locally Euclidean (i.e., around every point, there is a neighborhood that is topologically identical with the open unit ball in $\mathbb{R}^d$). As an example, in a one-dimensional manifold, every point has a neighborhood that is topologically identical with a line segment. A line is a 1D manifold, so is a curve. Similarly in a two-dimensional manifold, every point has a neighborhood that is like a disk. Examples include a plane, a Möbius band, and the sphere of the Earth. Locally at every point on the surface of the Earth, we see a plane (2D), but it actually curves back on itself and is globally a 3D sphere instead of a plane (i.e., 2D manifold in a 3D space).

Manifolds offer a powerful framework for dimension reduction. The key idea of dimension reduction is to find the most succinct low-dimensional structure that is embedded in a higher dimensional space. Many high-dimensional data sets can be modeled as sets of points lying close to a low-dimensional manifold. Given a set of data

points $x_1, x_2, \dots, x_N \in \mathbb{R}^D$, we can assume that they are sampled from a manifold with noise, that is,

$$x_i = \phi(y_i) + \varepsilon_i, \quad i = 1, \dots, N, \quad (1)$$

where $y_i \in \mathbb{R}^d$, d is usually far less than the original dimension D ($d \ll D$), and ε_i is noise. Function $\phi : C(\subset \mathbb{R}^d) \rightarrow \mathbb{R}^D$ represents the embedding of a d -dimensional manifold M in a D -dimensional space. Here C is a compact subset of $\mathbb{R}^d$ with open interior. Integer d is also called the *intrinsic dimension*. Manifold-based methodologies offer ways to find the embedded low-dimensional feature vectors, y_i , from the high-dimensional data points, x_i . Some methods also analyze how to reconstruct ϕ from x_i 's.

Manifolds also offer powerful tools in forecasting. The following simple example illustrates the key idea. Figure 1 plots a simulated time series data $x_t \in \mathbb{R}$, $t = 1, 2, \dots, 256$. There is no obvious rule to estimate the future value. However, in Fig. 2, where x_t versus x_{t-1} is plotted, it shows that all the 2D points, $\tau_t = (x_{t-1}, x_t)^T$, $t = 2, \dots, 256$, are around the solid curve (a one-dimensional manifold). That is,

$$\tau_t = \phi(y_t) + \varepsilon_t, \quad t = 2, \dots, 256,$$

where $y_t \in \mathbb{R}$ is one-dimensional. If we can reconstruct the manifold, ϕ , that is, if we can find the method to construct $(x_{t-1}, x_t)^T$, we can use this manifold structure to make one-step forecasting: $x_t = f(x_{t-1})$. Note here f is the relationship between x_t and x_{t-1} found from the reconstruction.

In general, we consider the forecasting framework:

$$x_t = f(x_{t-1}, \dots, x_{t-p}), \quad (2)$$

that is, predicting the value at the t th occasion via the previous p observed values. We have two challenges: (i) x_t can be high dimensional; (ii) the function f may not be in any known functional class. Challenge (i) can be addressed by dimension reduction. Evidently

Figure 1. A time series data set.

Figure 2. x_t versus x_{t-1} .

in some cases, nonlinear dimension reduction such as manifold-based methods can work well. It is not straightforward that challenge (ii) can be resolved via manifold-based methods as well. Note that if relation (Eq. 2) holds, then vectors $(x_{t-p}, \dots, x_t)$, for a range of t , reside on a low-dimensional manifold. Hence, determining f is equivalent to finding this manifold. After knowing the manifold, we can utilize reconstruction to predict according to Equation (2).

From the above, it is evident that we have two major tasks: finding the manifold from the high-dimension data, and reconstructing based on a learned manifold model. Note that there are many distinct manifold-based algorithms. It is important to understand their properties. We survey the existing manifold learning algorithms, and discuss their reconstructions. Their applications in forecasting are relatively underdeveloped. There is not much to be surveyed at this point, except for a few works such as Ref. 1. The promises of manifold-based forecasting have been realized by more and more researchers and practitioners.

This article is organized as follows. The section titled “Review of Manifold Learning Methods” reviews existing manifold learning methods, focusing on the dimensionality reduction. The methods surveyed include principal components analysis (PCA), multidimensional scaling, locally linear embedding (LLE), isometric feature mapping (ISOMAP), Laplacian eigenmaps, Hessian eigenmaps, and local tangent space alignment (LTSA). The section titled “Reconstruction” summarizes the reconstruction, which is a significant step for forecasting. The section titled “A Synthetic Example” gives a simple simulated example. The section titled “Another Framework” discusses another framework of utilizing manifold learning in forecasting for high dimensional data. Finally, the section titled “Conclusion” concludes the article.

REVIEW OF MANIFOLD LEARNING METHODS

On the basis of the discussion above, the first major task for manifold-based learning is to

find a coordinate system that characterizes the set of data points in a low-dimensional space. Given Model (1), the task is to find the estimation of the unknown lower-dimensional feature vectors y_i 's from the x_i 's. Note that x_i 's are the data points in $\mathfrak{R}^D$, while y_i 's are the points in $\mathfrak{R}^d$. With $d < D$ this task performs dimension reduction of the data points.

In this section, we review some manifold learning techniques, with the focus on dimension reduction. Our goal is to expose the reader to the issues involved and to describe some of the advanced approaches. We begin with the classical methods: PCA [2] and multidimensional scaling (MDS) [3–6] and then, the two fundamental nonlinear manifold searching methods: LLE [7,8] and ISOMAP [9,10]. LLE and ISOMAP appeared in the same issue of *Science* and inspired many other nonlinear manifold learning methods. We will provide a quick overview of three developments: Laplacian eigenmaps [11,12], Hessian eigenmaps (HLE, Hessian locally linear embedding) [13], and LTSA [14].

Owing to space, there are many other techniques not discussed here, such as principal curves and surfaces, nonlinear PCA, independent components analysis, self-organizing maps [15], generative topographic mapping (GTM) [16], and charting [17]. Descriptions of these techniques and additional references can be found in surveys [18,19]. The second survey [19] also provides applications of manifold learning methods on denoising, curve clustering, image detection, and the localization of sensor networks.

Principal Component Analysis (PCA)

PCA has been widely used for dimension reduction in a number of fields. A comprehensive discussion of PCA can be found in Ref. 2. PCA is closely related to singular value decomposition (SVD) [20]. These two techniques are the most classical methods in dimensional reduction. The key idea of PCA is to find the low-dimensional linear subspace that captures as much of the variability as possible.

Suppose $\mathbf{X} \in \mathfrak{R}^D$ is a random vector, whose variance–covariance matrix is Ω , that

is, $\text{Cov}(\mathbf{X}) = E\{[\mathbf{X} - E(\mathbf{X})][\mathbf{X} - E(\mathbf{X})]^T\} = \Omega$. Let $0 \leq \lambda_D \leq \lambda_{D-1} \leq \dots \leq \lambda_1$ be the ordered eigenvalues of Ω , and $U = [u_1, u_2, \dots, u_D]$ be the orthonormal matrix of eigenvectors, where u_i is the eigenvector corresponding to the i th largest eigenvalue λ_i .

PCA makes the following transformation $\mathbf{X} \rightarrow \mathbf{Y}$:

$$\mathbf{Y} = [u_1, \dots, u_d]^T \mathbf{X} = \begin{pmatrix} u_1^T \mathbf{X} \\ u_2^T \mathbf{X} \\ \vdots \\ u_d^T \mathbf{X} \end{pmatrix}, \text{ where } d \leq D.$$

The new vector $\mathbf{Y}$ is in a lower-dimensional space, $\mathfrak{R}^d$. It is provable that $\lambda_1, \lambda_2, \dots$, and λ_d are the variances of the transformed random variables $u_1^T \mathbf{X}, u_2^T \mathbf{X}, \dots$, and $u_d^T \mathbf{X}$. And these new variables keep the greatest possible proportion of the variation in the data. Consequently, they are called *principal components*.

PCA gives a natural dimension reduction. Consider an extreme case: if all the data lie in a low-dimensional linear subspace of a very high-dimensional space, PCA will find such a linear subspace, because the variations in the directions that are orthogonal to the embedded linear subspace will be equal to zero.

An evident disadvantage of PCA is that the embedded subspace has to be linear. For example, if the data are located on a circle in 3D, PCA will not be able to identify such a structure.

Multidimensional Scaling (MDS)

MDS is also often used for dimensionality reduction. MDS refers to a group of methods that have found a wide range of applications. Although a number of variations have been proposed, the key idea is the same: find a mapping to a low-dimensional space such that the pairwise distances between the observed points are preserved as much as possible. MDS starts from a distance (or dissimilarity) matrix, whose entry d_{lm} is the distance between the l th and m th objects. Let d'_{lm} denote the distance between the same two objects after they have been transformed

to the low-dimensional space. Classical multidimensional scaling (CMDS, that is, the model with only one distance matrix) tries to make the mapping by solving the following optimization problem:

$$\min \sum_{l \neq m} [d'_{lm} - d_{lm}]^2.$$

The objective function is also called *stress* in the MDS literature. The above stress is named *raw stress*, which is the most elementary loss function for MDS. Some other stress definitions include:

- Normalized stress:

$$\frac{\sum_{l \neq m} [d'_{lm} - d_{lm}]^2}{\sum_{l \neq m} d_{lm}^2};$$

- Kruskal's stress:

$$\frac{\sum_{l \neq m} [d'_{lm} - d_{lm}]^2}{\sum_{l \neq m} d_{lm}'^2};$$

- Weighted normalized stress:

$$\frac{\sum_{l \neq m} w_{lm} [d'_{lm} - d_{lm}]^2}{\sum_{l \neq m} w_{lm} d_{lm}'^2}; \text{ and so on.}$$

More techniques can be found in Ref. 3.

Those aforementioned stresses are all for the metric MDS, where the distance measure is quantitative. An intuitive example of the metric CMDS is to recover the relative positions of cities from the intercity mileages [21] (also see the example in Ref. 22). Soon after the introduction of metric MDS, non-metric MDS was proposed [4,6], in which, the data could be categorical so that the distance measure is at the ordinal level. In such case, a monotone transformation of the observed original distance, d_{lm} was applied to reproduce the general rank ordering of distances between the objects in the analysis.

For example, the generalized Kruskal stress becomes the following:

$$\frac{\sum_{l \neq m} [d'_{lm} - f(d_{lm})]^2}{\sum_{l \neq m} d_{lm}'^2},$$

where f is a monotone increasing function. For any fixed set of objects, f is specified. Again, we refer technical details to Refs 3,4, and 6.

We will not discuss the details of any specific MDS algorithm, except to say that the typical approach is to initially assign objects to lower-dimensional points in some manner and then try to modify the points to reduce the stress. In most existing MDS algorithms, a linear subspace is still the ultimate result.

MDS is a very useful tool when the interpoint distances need to be preserved. In ISOMAP, which is a method that will be described later, MDS is applied to geodesic distances. The above results in a nonlinear dimension reduction method. We will give more details in section titled "ISOMAP".

Locally Linear Embedding (LLE)

Given a set of data points $x_1, x_2, \dots, x_N \in \mathbb{R}^D$, LLE analyzes overlapping local neighborhoods in order to determine the local structure. The local structure is then preserved in the estimation of the lower-dimensional feature vectors $y_1, y_2, \dots, y_N \in \mathbb{R}^d$. The LLE algorithm is given below [7].

1. Find the k nearest neighbors of each data point based on Euclidean distance. Let N_i denote the set of indices of the k nearest neighbors of x_i .
2. Express each data point, x_i , as a linear combination of the k nearest neighbors. That is, find w such that the following objective function is minimized:

$$E(w) = \sum_i \left\| x_i - \sum_{j \in N_i} w_{ij} x_j \right\|^2,$$

where $\|\cdot\|$ is the l_2 norm and $\sum_{j \in N_i} w_{ij} = 1$.

It can be shown that the above can be solved as a least-squares problem. The weight w_{ij} indicates the contribution of the j th data point to the representation of the i th data point.

3. Find the low-dimensional points, y_i , which minimize the following objective function:

$$\Phi(y) = \sum_i \left\| y_i - \sum_{j \in N_i} w_{ij} y_j \right\|^2.$$

This step performs the actual dimensionality reduction. Note that the low-dimensional points, y_i , preserve the local convex representation, that is, the weights, w_{ij} , obtained from the last step are used in the construction of y_i . It can be shown that with some additional conditions, which make the problem well defined, the minimization task can be accomplished by solving a sparse $N \times N$ eigenvector problem. More specifically, the d eigenvectors associated with the d smallest nonzero eigenvalues provide an ordered set of orthogonal coordinates centered on the origin. We refer interested readers to Ref. 7 for the details of this formulation.

The LLE authors suggest that $k-b$ trees can be used to compute the k nearest neighbors efficiently [23]. The sparse eigenvector problem can be solved by fast algorithms as well [24]. One disadvantage of LLE is that it implicitly assumes that the manifold is convex. The methods that will be described later can overcome such a disadvantage.

ISOMETRIC FEATURE MAPPING (ISOMAP)

ISOMAP [9] is another nonlinear dimension reduction method. It can be viewed as an extension of metric MDS, by replacing the Euclidean distance with another type of distance. MDS and PCA are not good at dimensionality reduction when the points have a complicated, nonlinear relationship. However, ISOMAP can handle such data sets. The method works as follows:

1. Find the nearest neighbors of each data point $x_i \in \mathbb{R}^D, i = 1, 2, \dots, N$, based on Euclidean distance. Let N_i denote the set of indices of the nearest neighbors of x_i . There are two methods to find the nearest neighbors: either take the k nearest points of each point x_i , where k is a parameter (k nearest neighbors); or take all the points that are no more than a specified distance (ε) away from x_i (ε neighborhoods).
2. Redefine the distances between points to be the geodesic distance, which is the shortest curve that is on the manifold and connects the two points. The geodesic distances can be approximated as follows: First, construct a graph in which each point is a node, and two nodes x_i and x_j are connected if and only if $i \in N_j$ or $j \in N_i$. Then define the distance between x_i and x_j to be the sum of the arc lengths of the shortest chain connecting x_i and x_j . The distance is called a *graphical distance*.
3. Generate the low-dimensional points by calling a metric MDS on the new distance matrix.

The two kinds of neighborhoods in Step 1 have pros and cons. The k nearest neighbors has the advantage that it does not tend to disconnected graphs and the parameter k is easier to choose. However, it is less geometrically intuitive. The other choice, ε neighborhoods, is geometrically motivated, but often leads to graphs with several disconnected parts, and it is not obvious on how to choose ε .

The shortest chain (i.e., the graphic distance) in Step 2 can be computed via dynamic programming [25]. Bernstein *et al.* [26] show that the graphical distance is in some sense a good surrogate of the geodesic distance. Note that a graphical distance is computable from data, while geodesic distance is not observable.

Laplacian Eigenmaps

Laplacian eigenmaps are proposed in Refs 11 and 12. This work is a member of the ISOMAP-LLE family of algorithms, which build a graph incorporating neighborhood

information of the data set and compute for a low-dimensional representation of the data set that optimally preserves local neighborhood information in a certain sense. The justification of the Laplacian eigenmaps comes from the role of the Laplace–Beltrami operator and graph Laplacian, which are well known to specialists in spectral graph theory [27]. We first describe the algorithm for discrete data. Its justification will follow.

Given $x_1, x_2, \dots, x_N \in \mathbb{R}^D$, Laplacian eigenmaps looks for the embedded low-dimensional vectors $y_1, y_2, \dots, y_N \in \mathbb{R}^d$ by the procedure as follows:

1. Find the nearest neighbors of each data point, and use N_i to denote the set of indices of the nearest neighbors of x_i .
2. Similar to the second step in ISOMAP, construct a weighted graph in which each point is a node, and two nodes x_i and x_j are connected by an edge if and only if $i \in N_j$ or $j \in N_i$. For any pair of connected nodes i and j , assign following weight for the edge (heat kernel):

$$W_{ij} = \exp \left\{ -\frac{\|x_i - x_j\|^2}{t} \right\}, \quad (3)$$

where $\|\cdot\|$ is the l_2 norm, $t \in \mathbb{R}$ is a parameter.

3. Compute the eigenvalues and eigenvectors for the generalized eigenvector problem:

$$Lf = \lambda Gf, \quad (4)$$

where $f \in \mathbb{R}^N$ is eigenvector, $\lambda \in \mathbb{R}$ is eigenvalue, G denotes the diagonal weight matrix such that $G_{ii} = \sum_j W_{ji}$. Suppose W is the symmetric matrix with entries W_{ij} , then $L = G - W$ is the Laplacian matrix (graph Laplacian). Let $f_0, f_1, \dots, f_{N-1}$ be the solution vectors with corresponding eigenvalues $0 = \lambda_0 \leq \lambda_1 \leq \dots \leq \lambda_{N-1}$; that is,

$$\begin{aligned} Lf_0 &= \lambda_0 Df_0, \\ Lf_1 &= \lambda_1 Df_1, \\ &\vdots \\ Lf_{N-1} &= \lambda_{N-1} Df_{N-1}. \end{aligned}$$

4. Leave out the first eigenvector f_0 , which corresponds to eigenvalue 0. Use the next d eigenvectors for the maps:

$$x_i \rightarrow (f_1(i), f_2(i), \dots, f_d(i))^T.$$

The edge weight in Step 2 has an alternative choice: $W_{ij} = 1$ if nodes i and j are connected. This simplification avoids the necessity of choosing parameter t . The weight (Eq. 3) is motivated by heat flow, which is intimately related to the Laplace–Beltrami operator on differentiable functions on a manifold. The Laplace–Beltrami operator is the justification of the algorithm in the continuum.

An intuitive justification for solving the eigenvalue and eigenvector problem (Eq. 4) is to consider a “good” mapping minimizing the following objective,

$$\sum_{i,j} \|y_i - y_j\|^2 W_{ij} = \text{tr}(Y^T L Y). \quad (5)$$

Note that based on the definition of edge weight, W_{ij} is higher if nodes i and j are closer. Hence, the objective function (Eq. 5) punishes heavier if neighboring points x_i and x_j are mapped far apart. Therefore, minimizing Equation (5) keeps the “closeness” of the neighborhood. It is shown in Ref. 12 that the solution of Equation (5) provided by the matrix of eigenvectors corresponds to the lowest eigenvalues of the generalized eigenvalue problem (Eq. 4).

Belkin and Niyogi also explained in Ref. 12 that in the continuum, the Laplace–Beltrami operator on manifolds ($\mathcal{L}$) is analogous to the Laplacian of a graph (L). Chung [27] serves as a good reference. And, in order to optimally preserve locality on average, in the continuum, Ref. 12 shows that it leads to solving the following:

$$\underset{\|f\|_{L^2(M)}=1}{\text{argmin}} \int_M \|\nabla f(x)\|^2 = \underset{\|f\|_{L^2(M)}=1}{\text{argmin}} \int_M \mathcal{L}(f)f,$$

where the integral is taken with respect to the standard measure on a Riemannian manifold M , which is isometrically embedded in $\mathbb{R}^D$. f is a map from the manifold M to $\mathbb{R}$, which is twice differentiable. Note that minimizing

$\int_M \|\nabla f(x)\|^2$ corresponds directly to minimizing Equation (5) on a graph. The spectrum of L on a compact manifold M is known to be discrete. The rest of the dimension reduction is identical with the approach in the discrete case.

Hessian Eigenmaps (HLE)

The connection between spectral theory and dimension reduction, which is established in Laplacian eigenmaps, is very inspiring. This connection leads to the creation of Hessian eigenmaps (HLE) [13]. While all the previous methods do not give good results for nonconvex manifolds, Hessian eigenmaps overcomes the convexity limitation.

The conceptual framework of HLE in the continuum can be viewed as a modification of the Laplacian eigenmaps. Recall that in Laplacian eigenmaps, the following functional is considered:

$$\int_M \mathcal{L}(f) f.$$

In HLE, the above functional is replaced with

$$H(f) = \int_M \|H_f(m)\|_F^2 dm,$$

where M is the manifold, $m \in M$, $H_f(m)$ is the Hessian of function f , which is defined by orthogonal coordinates on the tangent plane of M , $\|\cdot\|_F$ denotes the Frobenius norm of a matrix. Therefore, $\mathcal{H}(f)$ measures the average, over the data manifold M , of the Frobenius norm of the Hessian H of f . Donoho and Grimes [13] proved that $\mathcal{H}$ has $(d+1)$ -dimensional null-space, consisting of the constant function and d -dimensional spaces spanned by the original isometric coordinates. This result establishes the fundamental correctness of HLE, while no similar result is found for Laplacian eigenmaps.

The algorithm proposed in Ref. 13 is based on a discrete estimation of tangent coordinates, the approximation to the tangent Hessian H , and the empirical version of the operator $\mathcal{H}$. The algorithm requires to solve N separate k -by- k eigen problems, where N is the sample size, and k is the neighborhood size. Additionally, similar to the LLE

algorithm, HLE finally needs to solve a single N -by- N sparse eigen problem. We omit the details here and refer the readers to the original article for details.

Local Tangent Space Alignment (LTSA)

LTSA [14] proposed by Zhang and Zha draws inspiration from the pioneering work in LLE. LTSA learns the local geometry of the manifold by constructing a local tangent space for each data point, which is similar to the first steps of HLE. However in HLE, the local tangent spaces are used to approximate Hessian, while in LTSA, the tangent subspaces are aligned together to give the global coordinates of the feature vectors. Given N, D -dimensional data points $x_1, x_2, \dots, x_N$, LTSA works as follows:

1. Identify k nearest neighbors for each data point $x_i, i = 1, 2, \dots, N$. As usual, let N_i denote the set of indices of the nearest neighbors of x_i . Let $X_i = [x_{i_1}, \dots, x_{i_k}]$ be a $D \times k$ matrix consisting of x_i 's nearest neighbors including x_i .
2. Obtain recentered neighborhoods. That is, for each data point, compute the $D \times k$ matrix $X^i = [x_{i_1} - \bar{x}_i, \dots, x_{i_k} - \bar{x}_i]$, where $\bar{x}_i$ is the average of all points in N_i . In matrix format, $X^i = X_i \left(I - \frac{1}{k} \mathbf{1}\mathbf{1}^T\right)$, where $\mathbf{1} \in \mathbb{R}^k$ is an all-one vector.
3. Find the d -dimensional affine subspace approximation of all the points in X_i by using the local tangent subspace. Specifically, suppose $\theta_{i_j} \in \mathbb{R}^d$ is the local parameterization for $x_{i_j}, i_j \in N_i$. The local parameterization matrix $\Theta_i = [\theta_{i_1}, \dots, \theta_{i_k}] \in \mathbb{R}^{d \times k}$ for the points in the neighborhood X_i is found by solving the following:

$$\begin{aligned} & \operatorname{argmin}_{\Theta_i, Q_i} \|X^i - Q_i \Theta_i\|_F^2 \\ & = \operatorname{argmin}_{\Theta_i, Q_i} \sum_{i_j \in N_i} \|(x_{i_j} - \bar{x}_i) - Q_i \theta_{i_j}\|_2^2, \end{aligned} \quad (6)$$

where $Q_i \in \mathbb{R}^{D \times d}$ forms an orthonormal basis of the tangent subspace, that is, $Q_i^T Q_i = I_d$. The solution of Q_i and Θ_i can be found by the SVD of X^i .

4. Compute the global feature coordinates $y_i \in \mathbb{R}^d, i = 1, 2, \dots, N$, by solving the following:

$$\underset{Y, L_i}{\operatorname{argmin}} \sum_{i=1}^N \|Y^i - L_i \Theta_i\|_F^2, \quad (7)$$

where $\|\cdot\|_F$ stands for the Frobenius norm of a matrix, $Y^i = [y_{i1} - \bar{y}_i, y_{i2} - \bar{y}_i, \dots, y_{iK} - \bar{y}_i]$ is the recentered matrix of y_i 's inside neighborhood N_i . The optimal L_i is given by $L_i = Y^i \Theta_i^+$. The solution for Y is provided by solving a sparse $N \times N$ eigenvector problem. Again, we omit the details here and refer the readers to Ref. 14 for details and fast implementations.

LTSA and LLE share the same structure: a local parameterization is first constructed and then a global alignment is computed. The difference is how the local information is summarized and preserved. There is another method similar to LTSA, charting [17], which is not equally well-developed mathematically.

RECONSTRUCTION

Given a new feature vector in the embedded low-dimensional space, the reconstruction method is used to find its counterpart in the high-dimensional space. That is, learning the mapping ϕ in Model (1). We have seen that reconstruction accuracy is critical for the application of manifold learning in the prediction. However, there are a limited number of reconstruction methods in the literature. For a specific linear manifold, the reconstruction can be easily made by PCA. For a nonlinear manifold, LLE reconstruction, which is derived in the similar manner as LLE, is introduced in Ref. 7. LTSA reconstruction and nonparametric regression reconstruction are introduced in Ref. 14. The summaries of these reconstruction methods are provided in the following.

PCA Reconstruction

Retrieving the old data is straightforward if the PCA transformation is originally used for dimension reduction. Recall that the PCA transform is $\mathbf{Y} = [u_1, \dots, u_d]^T \mathbf{X}$, where $\mathbf{X} \in \mathbb{R}^D$ is the original high-dimensional random point, $\mathbf{Y} \in \mathbb{R}^d, d \leq D$, is the lower-dimensional feature vector, $U_d = [u_1, u_2, \dots, u_d]$ contains the first d columns of the eigenvector matrix U . Recall that U is orthonormal, that is, $U^T U = I_D$. If we take all the eigenvectors in the transformation, that is, $\mathbf{Y} = U^T \mathbf{X}$, then getting the original data back is very easy: $\mathbf{X} = U \mathbf{Y}$. This formula also applies to the case when we do not have all the eigenvectors in the transformation ($d < D$). That is, we make the return trip through $\hat{\mathbf{X}} = U_d \mathbf{Y}$. The retrieved data $\hat{\mathbf{X}}$ has lost some information because $U_d U_d^T \neq I_D$. But since the PCA transformation preserves the greatest proportion of variance along the principle eigenvectors, the information lost is the variation in the other components (the other eigenvectors that were left out).

LLE Reconstruction

LLE reconstruction, which is introduced together with the LLE dimension reduction in Ref. 7, is derived in a similar manner as LLE. Given low-dimensional feature vectors $y_i \in \mathbb{R}^d, i = 1, 2, \dots, N$. Denote the new low-dimensional feature vector as y_0 . LLE reconstructs its high-dimensional correspondence x_0 as follows:

1. Identify the k nearest neighbors of y_0 among $y_1, y_2, \dots, y_N$. Let N_0 denote the neighborhood indices.
2. Express y_0 as a linear combination of the k nearest neighbors. That is, the following objective function is minimized.

$$E(w) = \left\| y_0 - \sum_{j \in N_0} w_j y_j \right\|^2, \quad (8)$$

where $\|\cdot\|$ is the l_2 norm and $\sum_{j \in N_0} w_j = 1$.

3. x_0 is constructed by $\hat{x}_0 = \sum_{j \in N_0} w_j x_j$.

Recall that LLE preserves the local convex representation (w_j 's) in the dimension reduction, the same structure is used in the reconstruction. Solving Equation (8) is equivalent to solving a linear system of equations. However, when $k > d$, the coefficient matrix associated with the system of linear equations is singular, which means that the solution is not unique. Saul and Rowe [28] propose to solve this issue by adding an identity matrix multiplied with a small constant to the coefficient matrix.

LTSA Reconstruction

The derivation of the LTSA algorithm does not consider nonlinear dimension reduction in isolation as merely constructing a nonlinear projection, but rather to combine it with the process of the reconstruction of the nonlinear manifold. Therefore, the LTSA reconstruction procedure appears along with the dimension reduction procedure in Ref. 14. In general, when the low-dimensional coordinates y_i are available, the LTSA reconstruction retrieves the high-dimensional data as follows:

1. Given $y_0 \in \mathbb{M}^d$, identify its closest point among $y_1, y_2, \dots, y_N$. Suppose y_i is the nearest neighbor.

2. Calculate the local tangent parameterization of y_0 :

$$\theta_0 = L_i^{-1}(y_0 - \bar{y}_i),$$

where $\bar{y}_i$ is the average of all y_{i_k} 's in the neighborhood N_i , L_i is the optimal alignment matrix that solves Equation (7).

3. Construct x_0 by $\hat{x}_0 = \bar{x}_i + Q_i \theta_0$, where Q_i solves Equation (6).

As seen from the aforementioned procedure, the LTSA reconstruction is exactly the reverse of LTSA dimension reduction. The errors of the reconstructed manifold depend on the sample errors, the local tangent subspace reconstruction errors, and the alignment errors. Zhang and Zha [14] prove that this dependence is linear.

Other Reconstructions

Many other reconstruction methods can be proposed. For example, in MDS, paired distance is preserved. We can reconstruct the original data by keeping those distances too. LLE reconstruction can be used after a HLLE dimension reduction. In Ref. 14, a nonparametric regression reconstruction is proposed. Specifically, once y_i are computed for each of the data points x_i , some nonparametric regression methods such as local polynomial regression can be applied to $\{(y_i, x_i)\}_{i=1}^N$ to

Figure 3. First 100 data points in the generated time series.

Figure 4. Last 100 data points in the generated time series.

construct the manifold underlying the set of points x_i . That is, we can assume that the manifold function ϕ in Equation (1) is locally polynomial, and we construct ϕ separately in each neighborhood.

A SYNTHETIC EXAMPLE

For illustration purpose, we consider a length-4000 time series, which follows the

following rule: $x_i = \frac{x_{i-2}}{\sqrt{x_{i-2}^2 + x_{i-1}^2}} + \varepsilon_i$, where $i = 3, \dots, n$, $\varepsilon_i \sim \text{Normal}(0, 0.01)$. The first and last 100 data points are plotted in Figs 3 and 4.

Evidently, from x_{i-1} and x_{i-2} , there is a fundamental rule to determine the mean value of x_i . However, such a rule is hidden in the data. If we plot x_{i+1} against x_i , we observe a circle as in the following Fig. 5. Note the value of x_{i+1} cannot be uniquely determined

Figure 5. Plot of points against from the generated time series.

Figure 6. Plot of three consecutive observation points from the time series.

Figure 7. Illustration of the learned model based on the three-tuple data points from the time series.

by x_i , hence three consecutive observations, (x_i, x_{i+1}, x_{i+2}) , must be considered.

The 3D plot of points (x_i, x_{i+1}, x_{i+2}) is displayed in Fig. 6. The embedded underlying rule can be seen vaguely. However, we need to compute for the underlying rule from the data. Note that it is too opportunistic to assume any parametric form to the underlying rule. Hence a manifold-based learning method is favored, because it requires little presumption.

Applying a manifold-based learning method—we utilized the Local linear projection (LLP) method in Huo and Chen [22]—the underlying structure is learned to be nearly a 3D circle, which is plotted in Fig. 7. This is also consistent with the way the time series is generated.

Given the learned model, one can implement a prediction scheme on this time series. We omit the details of forecasting here, because it is evident from the context.

Figure 8. The conceptual flowchart of modeling and forecasting with manifold learning from Ref. 1.

ANOTHER FRAMEWORK

There are not many manifold-based forecasting models in the literature. Recently, Chen *et al.* applied LLE and LLE reconstruction in predicting the electricity price curve [1]. However, their framework is different with the procedure we explained in the introduction and the previous section. We review their idea in the following.

The time series data (electricity price curve) in Ref. 1 is high dimensional. Each data point contains daily or weekly price changes. Modeling the daily or weekly price curve as a whole can provide great advantages for forecasting in a longer horizon from days to weeks. Chen *et al.* [1] use manifold learning methods to analyze the intrinsic structures of the high-dimensional price curves in the low-dimensional space (dimension reduction), and then make the forecasting on the low-dimensional representation. Finally, the low-dimensional prediction is mapped back to the original

high-dimensional space by manifold reconstruction. Figure 8 illustrates the conceptual flowchart of their modeling approach.

It can be seen that the forecasting in the above model is still the classical parametric or nonparametric models such as autoregressive integrated moving average model (ARIMA) or artificial neural networks. The idea here is different from the illustration in Figs 1 and 2. However, the two procedures we have surveyed, dimension reduction and manifold reconstruction are still very important in this framework.

In general, the task of analytically forecasting the dynamics of high-dimensional time series is daunting. The above framework provides a useful strategy for the analysis. The real-world forecasting is difficult also because of the irregular format of the prediction function f [2]. We hope our framework in the introduction can provide new insight into the problem and stimulate a new direction for work in manifold-based forecasting.

CONCLUSION

Manifold-based forecasting gives a promising alternative to existing forecasting approaches. To correctly utilize it, modelers must understand different applicable domains for different algorithms. We did a survey on some widely known manifold-based learning algorithms. We also reviewed their corresponding reconstruction strategies. We hope to draw more attention to this field of research from both methodologists and practitioners.

MODELING UNCERTAINTY IN OPTIMIZATION PROBLEMS

ANDY PHILPOTT

Department of Engineering Science,
University of Auckland, Auckland,
New Zealand

INTRODUCTION

This expository article discusses approaches for modeling optimization problems that involve uncertainty. The emphasis of the article is on motivation and intuition rather than technical completeness. By virtue of its length, the article is inevitably incomplete, and the reader is advised to look at other articles in this encyclopedia to explore the richness of modeling approaches that this article can only hint at.

How to model real decision problems using optimization models depends on the exact form of the problem being faced, and so it is difficult to give a general description of modeling techniques without some context in which to view the techniques. For this reason, we have chosen to illustrate the modeling approaches we discuss by placing them in the context of optimization of some models of electricity generation.

Optimization problems that involve uncertainty fall into several broad classes that admit different modeling approaches. A good starting point is to consider any system with random effects that can be simulated. As an example consider a simple unit commitment problem in which the owner of a thermal generation unit and a wind farm must decide ahead of time whether to start up their thermal unit to meet a known future demand. If the wind blows enough then there will be sufficient power to meet the load, and so the cost incurred by the startup will be unnecessary. On the other hand, if the wind does not blow, and the unit is not started then the owner will incur some penalty of

not supplying the demand. The decision in this case is a simple binary choice, and our model should enable the decision-maker to make the correct choice.

The natural question to ask at this point is “how do we determine the correct choice?” Since there are only two alternatives, one can investigate all the implications of making each choice and compare them. We suppose here, and throughout the rest of the article that the best choice would be clear if there were no uncertainty in the model. In other words, if we had a perfect forecast of wind then our choice would be to start the thermal plant only if the cost of doing so were smaller than the cost of shortage that the startup avoids. (Of course there are settings in which we might consider other criteria such as environmental impact, in which case we seek the solution to a multicriteria optimization problem, but we shall not be concerned with this aspect in this article, and the reader should consult, for example, Figueira *et al.* [1].)

If a perfect forecast of wind is not available, then one is faced with the problem of determining the best choice under uncertainty. A good question to ask at this point is “can we construct or estimate a probability distribution for uncertain wind events?” for example, from historical data and/or meteorological models. If so, then we say that the uncertainty is *probabilistic*. (It is well known that economists like to distinguish between *risk* and *uncertainty*, where risk involves events having probability distributions, and uncertainty is a situation for which we have no previous data or experience so that it is impossible to model statistically, but since we use the word “risk” in a different sense, we call these probabilistic and nonprobabilistic uncertainty.)

Let us first consider the case of probabilistic uncertainty. The distribution of this might take the form of some well-known distribution from a parametric family (such as a lognormal distribution) or it might be empirically determined (e.g., from a Monte Carlo simulation). The existence of such

a distribution means in principle that the probability distribution of total cost of either switching on the unit, or keeping it off can be computed. Armed with these distributions the decision-maker can express a preference for one to determine the best decision. The message here is that optimization under uncertainty with known probability distributions is about choosing between a (possibly infinite) set of probability distributions of total cost. Furthermore, as we discuss in this article, the existence of probability distributions allows us to use probability theory to explore mathematically different ways of making this choice. We shall discuss this more fully in the section titled “Optimization Modeling with Probability.”

How does one handle nonprobabilistic uncertainty? On one hand the decision-maker might be faced with a collection of data points with insufficient a priori knowledge to confidently determine a probability distribution from which these data are drawn. In our unit commitment example, we may have only 10 observations of previous wind outcomes. In this context the modeling choices become less obvious. On one hand, the collected data could be viewed as an empirical discrete distribution. In our example, this would give rise to 10 wind outcomes (or *scenarios*) each with probability 0.1. Even if they were not evenly weighted, at least we would want to investigate the candidate decisions in each of the 10 scenarios to see what the cost would have been in these scenarios. The decision-maker can then choose the vector of 10 outcomes that is preferred. How to do this soundly is less obvious when there is no probability distribution, but there is a rich literature on making these choices according to different criteria. We shall return to this in the section titled “Optimization modeling without probability.”

The final form of uncertainty the decision-maker might be confronting is that for which there is no probability distribution, or reliable data, or even a coherent understanding. Uncertain events might occur that are not even foreseen—the so-called *black swans* (the probability of a swan being white was 1 until black swans were discovered in Western

Australia) that have been popularized in the recent book by Nicolas Taleb [2] that warns of the dangers of quantitative modeling in finance. However, faced with such comprehensive uncertainty, there is little one can do from an operations research perspective. This does not mean that one should be entirely solipsistic—stress testing candidate decisions under some outlandish scenarios can yield valuable insights even those might be supposed to occur with miniscule probability. Nevertheless, the black swan will, by definition, always elude the analyst.

The remainder of this article is laid out as follows. The next section gives an overview of probabilistic modeling in optimization problems. The section titled “Optimization Modeling without Probability” deals with the treatment of uncertainty when probability distributions are not available. The final section “Bibliographical Notes” provides some brief bibliographical references.

OPTIMIZATION MODELING WITH PROBABILITY

Probabilistic optimization models take advantage of the fact that probability distributions governing the data are known or can be estimated. In this section, we will discuss how to model these with reference to problem examples drawn from electricity generation.

To begin the discussion we recall the unit commitment problem discussed in the section titled “Introduction,” and formulate this mathematically. For simplicity, assume that there is a single hour of demand d MW to be met. Suppose, the thermal unit has a capacity g MW, a startup cost of $\$h$, a running cost of $\$/\text{MWh}$, and the supply of wind power is the random variable $S(\omega)$, where $\omega \in \Omega$ denotes a random wind event for the hour in question. Finally, suppose that any shortages of electricity cost $\$/\text{MWh}$. Let

$$z = \begin{cases} 1, & \text{if the unit is started} \\ 0, & \text{if the unit is not started} \end{cases},$$

and suppose $X(\omega)$ is the (random) power generated by the unit. Observe that in any

Figure 1. Plot of $C(0, \omega)$ (dotted) and $C(1, \omega)$ (solid) for unit commitment example.

outcome ω , the optimal choice of $X(\omega)$ is

$$X(\omega) = z \min \{g, \max(0, d - S(\omega))\}.$$

Then the cost of decision z in outcome ω is

$$C(z, \omega) = hz + cz \min \{g, \max(0, d - S(\omega))\} + s \max(0, d - S(\omega) - gz).$$

As discussed in the section titled “Introduction,” a decision-maker can compare $C(0, \omega)$ and $C(1, \omega)$ for every realization of ω and choose which decision they prefer. As an illustration, these functions are plotted in Fig. 1 for $h = 20, c = 1, g = 5, d = 6$, and $s = 10$ over the range $S(\omega)$ from 0 to 10.

They show that not committing the unit is a costly decision when wind generation is low, but is inexpensive when wind becomes plentiful. Conversely, committing the unit incurs an expense but saves on shortage cost, except when $S(\omega)$ is less than 1. From these plots alone it is not clear which is the better decision.

If a probability distribution is known for wind outcomes ω , then it is possible to analyze the choices in more detail. For example, if there is zero probability of observing wind generation less than $\frac{34}{9}$ MWh, then it is less costly to leave the unit off, as this policy is less costly with probability 1. This approach can be explored further by attempting to order the probability distributions that emerge from different decisions. The theory of *stochastic dominance* gives

a methodology for doing this. A random variable C_1 is said to *stochastically dominate* random variable C_2 to *first-order* if for every x , $\Pr(C_1 \leq x) \leq \Pr(C_2 \leq x)$. When minimizing cost we might seek a policy that gives rise to a (random) objective function that is dominated by those of every alternative policy.

In the unit commitment problem suppose that $S(\omega)$ has a uniform distribution on $[0, 10]$, then $C(0, \omega)$ has distribution function

$$\Pr(C(0, \omega) \leq x) = \begin{cases} 0, & x \leq 0 \\ 0.4 + 0.01x, & 0 < x \leq 60 \\ 1, & 60 < x \end{cases}$$

and $C(1, \omega)$ has distribution function

$$\Pr(C(1, \omega) \leq x) = \begin{cases} 0, & x \leq 20 \\ -1.6 + 0.1x, & 20 < x \leq 25 \\ 0.65 + 0.01x, & 25 < x \leq 35 \\ 1, & 35 < x. \end{cases}$$

as shown in Fig. 2.

It is easy to see that neither $C(0, \omega)$ nor $C(1, \omega)$ is first-order stochastically dominant. This example illustrates that this is a very strong form of optimality, and often precludes finding a suitable solution. (Second- and higher-order stochastic dominance relations can be defined that admit more possible solutions; we shall not discuss these here but refer the reader to Shapiro *et al.* [3].)

As an alternative to stochastic dominance, we might constrain the policies that we are prepared to accept to those that have a high

Figure 2. Cumulative distribution functions of $C(0, \omega)$ (dotted) and $C(1, \omega)$ (solid).

cost only with low probability. This is an example of a *chance constraint*, which takes the form

$$\Pr(C(z, \omega) \leq \tau) \geq 1 - \alpha.$$

For example, if the probability distribution of wind outcomes $S(\omega)$ is uniform on $[0, 10]$, then we could constrain z to satisfy

$$\Pr(C(z, \omega) \leq 30) \geq 0.9.$$

Since $\Pr(C(0, \omega) > 30) = 0.3$, and $\Pr(C(1, \omega) > 30) = 0.05$, this constraint is satisfied by $z = 1$, but not $z = 0$.

The choice of a policy becomes more obvious in settings in which decisions are made repeatedly in essentially the same circumstances, and the objective is to come up with a decision that will perform well on average. In our unit commitment example this would be the case if the commitment decision was being repeated every day or every few hours. In this setting the goal is to find some policy that minimizes the expectation $\mathbb{E}[C(z, \omega)]$ of $C(z, \omega)$. This objective is justified by the law of large numbers for infinitely repeated trials which implies that a policy that minimizes expected costs will result in the minimum long-run average cost. In the example with a uniform distribution of wind outcomes, $\mathbb{E}[C(1, \omega)] = 22.25$ and $\mathbb{E}[C(0, \omega)] = 18$, and so the minimum expected cost policy is to keep the unit off.

The mathematical expectation operator is an example of a *risk measure*, a function $\rho(Z)$ from a space of random variables to $\mathbb{R}$. It assigns a score to any random variable Z that can then be ranked against the scores of others. In the example $Z_0 = C(0, \omega)$, and $Z_1 = C(1, \omega)$, and $\rho(Z_0) = 18$ is preferable to $\rho(Z_1) = 22.25$. When modeling optimization problems it is often crucial that the risk measure be convex and monotone, so that efficient numerical procedures can be applied to solve the problem. More generally, a risk measure is called *coherent* if it has the following properties.

1. It is convex, that is, if Z_1 and Z_2 are two random variables and $t \in [0, 1]$, then

$$\begin{aligned} \rho(tZ_1 + (1-t)Z_2) \\ \leq t\rho(Z_1) + (1-t)\rho(Z_2). \end{aligned}$$

2. It is monotone, that is, if Z_1 and Z_2 are two random variables such that with probability 1 $Z_2 \geq Z_1$, then $\rho(Z_2) \geq \rho(Z_1)$.
3. It is positively homogeneous, that is, if Z is a random variable and $t > 0$, then $\rho(tZ) = t\rho(Z)$.
4. It has the (translation equivariance) property: $\rho(Z + a) = \rho(Z) + a$ for any $a \in \mathbb{R}$.

Properties (1) and (2) ensure that if $C(\cdot, \omega)$ is convex for almost every ω , then the function $f(z) := \rho(C(z, \omega))$ is also convex.

As mentioned above, the expected cost is an appropriate risk measure for an optimization problem that is solved repeatedly as variations of cost around the expected cost will balance out in the long run. For a solution that is to be used only once, we might seek to control this random variation, especially if it produces high costs. One way of doing this is by adding a chance constraint of the form

$$\Pr(C(z, \omega) \leq \tau) \geq 1 - \alpha. \quad (1)$$

Unfortunately this is not convex in general, and so does not correspond to a coherent risk measure.

The Constraint (1) can be approximated by

$$\text{CVaR}_{1-\alpha}(C(z, \omega)) \leq \tau,$$

where CVaR is called the *conditional value at risk*, defined to be

$$\text{CVaR}_{1-\alpha}(Z) := \inf_{t \in \mathbb{R}} \left\{ t + \alpha^{-1} \mathbb{E} [\max\{0, Z - t\}] \right\}.$$

It can be shown that the coherent measure CVaR is the tightest safe convex approximation to Equation (1). In the example, the CVaR of each unit commitment decision at level 0.95 is respectively

$$\begin{aligned} & \text{CVaR}_{0.95}(C(0, \omega)) \\ &= \inf_{t \in \mathbb{R}} \left\{ t + 20 \mathbb{E} [\max\{0, C(0, \omega) - t\}] \right\} \\ &= \inf_{t \geq 0} \left\{ -11t + 360 + \frac{1}{10}t^2 \right\} = \frac{115}{2}, \\ & \text{CVaR}_{0.95}(C(1, \omega)) \\ &= \inf_{t \in \mathbb{R}} \left\{ t + 20 \mathbb{E} [\max\{0, C(1, \omega) - t\}] \right\} \\ &= \inf_{t \geq 25} \left\{ -6t + \frac{245}{2} + \frac{1}{10}t^2 \right\} = \frac{65}{2}, \end{aligned}$$

so with this risk measure there is less risk in running the unit. Observe in this example that the underlying (discrete) optimization problem is not convex, and so the use of a coherent risk measure here does not retain

convexity as it would if applied to a linear program.

Finally, we mention the classical approach to modeling risk that can be traced back to Bernoulli [4] that uses utility and disutility functions as risk measures. (Here we speak of disutility when minimizing and utility when maximizing). In a minimization problem like our unit commitment problem, the risk measure $\rho(Z)$ is defined to be $\mathbb{E}[u(Z)]$ for some disutility function u . Typically, utility functions are chosen to be concave and disutility functions are convex. This represents aversion to risk on the part of decision-makers. To illustrate this, consider the unit commitment example with the disutility function $u(z) = z^2$. Then

$$\mathbb{E}[u(C(0, \omega))] = 720, \quad \mathbb{E}[u(C(1, \omega))] = 505,$$

so with this risk measure the decision-maker would prefer to run the unit.

The unit commitment example we have been studying involves choosing from two possible decisions, to run the thermal unit or not to run it. Implicit in each of these choices is an operating level $X(\omega)$ for the plant under each wind realization. Because of its cost structure, our model can assume this to be the minimum level required to meet demand minus wind generation if this does not exceed the capacity of the unit.

In many circumstances this implicit optimization is not possible, and for each unit commitment decision we must solve a dispatch problem to determine the optimal level at which to run each plant. This leads to the widely studied *two-stage stochastic program with recourse*, where the first stage of the problem determines the unit commitment and the second stage, or recourse problem, determines the optimal generation level in each scenario given this unit commitment decision.

In general, the classical two-stage linear stochastic programming problem can be formulated as

$$\min_{x \in X} \{c^T x + \mathbb{E}[Q(x, \xi)]\}, \quad (2)$$

where $Q(x, \xi)$ is the optimal value of the second-stage problem

$$\min_y q^\top y \text{ subject to } Tx + Wy \leq h. \quad (3)$$

Here, x is the first-stage decision vector that must lie in some set X , $y \in \mathbb{R}^m$ is the second-stage decision vector and $\xi = (q, T, W, h)$ contains the data of the second-stage problem. In this formulation, at the first-stage we have to make a “here-and-now” decision x before the realization of the uncertain data ξ , viewed as a random vector, is known. At the second stage, after a realization of ξ becomes available, we optimize our behavior by solving an appropriate optimization problem.

An important practical question is whether the formulated problem can be solved numerically. In that respect the standard approach is to assume that random vector ξ has a finite number of possible realizations or scenarios, say $\xi_1, \dots, \xi_K$, with respective (positive) probabilities $p_1, \dots, p_K$. Then the expectation can be written as the summation

$$\mathbb{E}[Q(x, \xi)] = \sum_{k=1}^K p_k Q(x, \xi_k), \quad (4)$$

and, moreover, the two-stage problem (2) and (3) can be formulated as one optimization problem

$$\begin{aligned} \min_{x, y_1, \dots, y_K} \quad & c^\top x + \sum_{k=1}^K q_k^\top y_k \\ \text{s.t.} \quad & x \in X, T_k x + W_k y_k \leq h_k, k = 1, \dots, K. \end{aligned} \quad (5)$$

In the above formulation (5), we make one copy y_k , of the second-stage decision vector, for every scenario $\xi_k = (q_k, T_k, W_k, h_k)$. By solving Equation (5), we obtain an optimal solution $\bar{x}$ of the first-stage problem and optimal solutions $\bar{y}_k$ of the second-stage problem for each scenario ξ_k , $k = 1, \dots, K$. Given $\bar{x}$, each $\bar{y}_k$ gives an optimal second-stage decision corresponding to a realization $\xi = \xi_k$ of the respective scenario.

In practice this recourse structure exists at many stages, and the two-stage model is an

approximation of a more complicated process in which observations of uncertain parameters occur over time, and decisions are made that adapt to these observations. In mathematical terms, the random variables form a *stochastic process*, and the decisions to be made must be measurable with respect to the filtration defined by this process.

As an example of a problem with such a structure consider the problem of controlling a reservoir with maximum volume a and initial storage r , that is used for hydroelectricity generation in conjunction with a thermal unit to minimize the expected cost of meeting demand over some planning horizon $t = 1, 2, \dots, T$. For simplicity, we assume that the thermal unit has zero startup cost but capacity g MW, and a running cost of $\$c/\text{MWh}$. We also assume that (known) electricity demand is $d(t)$, $t = 1, 2, \dots, T$, and the supply of wind power is zero. As before suppose that any shortages of electricity cost $\$s/\text{MWh}$.

The new feature of our model is a random inflow sequence $I(t)$, $t = 1, 2, \dots, T$, that may be stored for electricity generation through a turbine with capacity b MW. This gives the following model:

MSP:

$$\begin{aligned} \min \quad & \mathbb{E} \left[\sum_{t=1}^T cX(t) + sY(t) \right] \\ \text{s.t.} \quad & X(t) + U(t) + Y(t) = d, \\ & t = 1, 2, \dots, T, \\ & R(t) = R(t-1) - \beta U(t) - V(t) + I(t), \\ & t = 1, 2, \dots, T, \\ & 0 \leq R(t) \leq a, \quad R(0) = r, \\ & t = 1, 2, \dots, T, \\ & 0 \leq X(t) \leq g, \quad t = 1, 2, \dots, T, \\ & 0 \leq U(t) \leq b, \quad t = 1, 2, \dots, T, \\ & V(t) \geq 0, \quad t = 1, 2, \dots, T. \end{aligned}$$

Here, $X(t)$ is the thermal generation, $U(t)$ is hydro generation, $Y(t)$ is unserved demand, $V(t)$ is spill, and $R(t)$ is reservoir storage at the end of period t , all of which are random variables. The parameter $\beta \text{ m}^3/\text{MWh}$

converts the electric power generated in a period into the corresponding volume of water released.

This general formulation MSP can be interpreted in many ways depending on how the random inflows $I(t)$ are modeled. A possible model could consider all T inflows to be revealed to the decision-maker at once, who plans a (possibly different) least cost electricity generation schedule for each realization of inflows and then computes its cost. This *wait-and-see* version of the problem is of course unrealistically optimistic, and will give policies that will be unable to be implemented unless perfect foresight is available. In contrast, a *here-and-now* version of the problem might seek a fixed plan of thermal generation decisions $x(t)$ that must be feasible for all realizations of $I(t)$ and minimizes $\sum_{t=1}^T cx(t) + \mathbb{E}[\sum_{t=1}^T sY(t)]$. Because of its inflexibility, this model is likely to result in expensive policies.

Between these extremes there are many models that incorporate flexibility in the policies. The modeling choice then becomes a trade-off between realism and computational tractability. If $I(t)$ follows a general stochastic process then MSP becomes a multistage stochastic linear program. Traditional stochastic programming methodologies for solving these models use *scenario-trees*, each of which approximates the stochastic process by one defined on a finite set of outcomes in each stage leading to a large-scale mathematical programming problem. If either the number of stages or dimension of the random variable becomes large, then scenario-tree approximations can be quite poor, and hence this approach has serious limitations for many realistic-sized problems.

On the other hand, when $I(t)$ is stage-wise independent or is a Markov process, MSP can be treated as a Markov decision problem that can be attacked using methods of dynamic programming. For the reservoir problem, we define $Q_{t-1}(r)$ to be the minimum expected thermal and shortage cost incurred over the period $t, t+1, \dots, T$, if the reservoir storage at the end of period $t-1$ is r , and an optimal policy is followed. In the case where $I(t)$ is stage-wise independent this gives the

recursion:

$$Q_{t-1}(r) = \text{DP}(t):$$

$$\begin{aligned} \min \quad & cx(t) + sy(t) + \mathbb{E}[Q_t(R(t))] \\ \text{s.t.} \quad & x(t) + u(t) + y(t) = d, \\ & R(t) = r - \beta u(t) - V(t) + I(t), \\ & 0 \leq R(t) \leq a, \\ & 0 \leq x(t) \leq g, \\ & 0 \leq u(t) \leq b, \\ & V(t) \geq 0. \end{aligned}$$

Solving such a recursion in general is possible only if the state variable r has low dimension.

We conclude here by discussing the advantages of modeling a multistage decision problem as a dynamic program rather than a multistage stochastic program. As mentioned above scenario-tree models become computationally intractable as the number of stages and random outcomes grows. In contrast, dynamic programming can admit many stages, but suffers from a curse of dimensionality in the state variables. Hence, there are computational advantages when the state space is of low dimension.

A second advantage of dynamic programming is that it gives a state-feedback policy, rather than an open-loop set of actions adapted to the filtration of the stochastic process. This makes simulation much easier. To simulate a multistage stochastic programming solution in a rolling horizon implementation requires a model like MSP to be generated and solved as each stage unfolds, a considerable computational effort considering that $T-1$ such solves are required for a single realization of random outcomes over T stages. In contrast, dynamic programming, given $Q_t(\cdot)$ would solve $\text{DP}(t)$ at each stage in such a simulation, a much less intensive effort.

OPTIMIZATION MODELING WITHOUT PROBABILITY

In this section, we give a brief discussion of optimization under uncertainty without

using probability distributions. The principle in this setting is to make decisions that are somehow *robust* in the face of variations in data. Different modeling approaches are available here, and we give a brief overview, returning to the unit commitment problem discussed in the section titled “Optimization Modeling with Probability” as an illustration. Recall the plot of the cost outcomes of the alternative decisions, shown in Fig. 1.

The classical *minimax* criterion used in modeling without probability seeks to minimize the worst case. In the unit commitment example, the worst-case cost is 60 for $z = 0$ and 35 for $z = 1$, hence $z = 1$ is the preferred solution under a minimax objective. Observe that this would still be the minimax solution even if $C(0, \omega)$ was 36 when $S(\omega) = 0$, and zero for $S(\omega) > 0$, which would make the choice of $z = 1$ an overly cautious solution.

An alternative criterion is to minimize maximum regret. Here *regret* is defined to be the difference in cost between the decision taken and the optimal decision with hindsight. The maximum regret for the decision $z = 1$ in the example is 20, which occurs when $S(\omega) \geq 6$. The maximum regret for the decision $z = 0$ in the example is 25, which occurs when $S(\omega) \leq 1$. Thus we should choose $z = 1$. Observe that if $C(0, \omega)$ was 36 when $S(\omega) = 0$, and zero for $S(\omega) > 0$ then the maximum regret for the decision $z = 0$ in the example is 1, which makes it preferred to $z = 1$. This instance does however illustrate a paradox with this approach. If $C(0, \omega)$ was 56 when $S(\omega) = 0$, and zero for $S(\omega) > 0$ then the maximum regret for the decision $z = 0$ is 21, which makes $z = 1$ preferred again, even though it is a worse decision in every outcome except when $S(\omega) = 0$. This highlights the advantages of a probabilistic model that can quantify the trade-offs between different outcomes.

Since the minimax criterion is widely recognized as being too conservative, there have been a number of efforts to make it less. *Robust optimization* applies the minimax criterion to a subset of possible outcomes called an *uncertainty set*. Formally robust optimization seeks the solution to the semi-infinite

program

$$\begin{aligned} \text{RP: } \min_x \quad & f(x) \\ \text{s.t.} \quad & g(x, u) \leq 0, \quad u \in U, \end{aligned}$$

where the functional dependence of g on u and uncertainty set U is specially constructed so that this problem can be solved using an efficient algorithm.

In the unit-commitment example, one might choose

$$U_1 = \{\omega \mid 2 \leq S(\omega) \leq 8\},$$

and solve, for example,

$$\begin{aligned} \text{RP: } \min_{x,z} \quad & x \\ \text{s.t.} \quad & C(z, \omega) \leq x, \quad \omega \in U_1. \end{aligned}$$

This has solution $z = 1$. On the other hand choosing

$$U_2 = \{\omega \mid 4 \leq S(\omega) \leq 10\},$$

gives optimal solution $z = 0$.

There has been considerable discussion in the literature on the relative merits of robust optimization and chance-constrained programming. The latter approach as part of the optimization seeks the best set U of outcomes with probability $1 - \alpha$ for which RP gives the least cost, and hence from a modeling approach it is richer. Thus, if we assume a uniform distribution in the above example, the chance-constrained problem

$$\begin{aligned} \text{CP: } \min_{x,z} \quad & x \\ \text{s.t.} \quad & \Pr(C(z, \omega) \leq x) \geq 0.6, \end{aligned}$$

has optimal solution $z = 0$, corresponding to the optimal choice of uncertainty set U_2 .

On the other hand, the optimal set U may be poorly behaved (making even RP for this U a difficult problem to solve) and so a chance-constrained model might prove impossible to solve for instances with lots of variables. In this case, robust optimization provides an alternative modeling approach.

BIBLIOGRAPHICAL NOTES

The concept of two-stage linear stochastic programming with recourse was introduced in Beale [5] and Dantzig [6]. For the theory and applications of two-stage and multistage stochastic programming, see the monographs [3,7–10]. Chance-constrained problems were introduced in Charnes *et al.* [11]. For a thorough discussion and development of that concept we may refer to Prékopa [8]. An introductory treatment is available in the on-line tutorial by Henrion [12].

The first mathematical discussion of risk aversion (using utility functions) is often attributed to Bernoulli [4]. The concept of utility was formally defined and expounded by von Neumann and Morgenstern [13]. Coherent risk measures were first introduced by Artzner *et al.* [14]. The approach of using CVaR for approximating chance constraints is due to Rockafellar and Uryasev [15].

Robust optimization models using ellipsoidal uncertainty sets were introduced by Ben Tal and Nemirovski [16], who showed how to formulate these as second-order cone problems. An alternative approach is due to Bertsimas and Sim [17].

Acknowledgments

Much of this article is drawn from the material in the on-line tutorial article [18]. The author would like to acknowledge the contributions of Alexander Shapiro to this work.

MODELS AND BASIC PROPERTIES

RENÉ HENRION
Weierstrass Institute,
Berlin, Germany

Probabilistically Constrained Programming (also known as *Chance-Constrained Programming*) belongs to the major approaches for dealing with random parameters in optimization problems. Typical areas of application are engineering and finance, where uncertainties like product demand, meteorological or demographic conditions, currency exchange rates and so on enter the inequalities describing the proper working of a system under consideration. The main difficulty of such models is due to the fact that decisions have to be taken prior to the observation of the random variables (“here and now”). A naive way to circumvent this difficulty would consist in replacing the random variables by their expectations estimated from historical data. However, then the resulting decisions would severely lack robustness. This could result in frequent violations of constraints when randomness becomes manifest. On the other hand, in a here-and-now situation, one can hardly find a decision which would definitely exclude later constraint violation. And if so, such decisions typically turn out to involve unreasonably high costs, just in order to hedge against extremely rare events.

Sometimes, such constraint violation can be balanced afterward by some compensating decisions taken in a second stage. For instance, taking recourse to pumped storage plants or buying energy on the liberalized market is an option for power-generating companies that are faced with unforeseen peaks of electrical load. As long as the costs of compensating decisions are known, these may be considered as a penalization for constraint violation. This idea leads to the important class of *two-stage* or *multistage stochastic programs* (see the sections titled “Two-Stage Stochastic Programming” and

“Multistage Stochastic Programming” in this encyclopedia).

In many applications, however, compensations simply do not exist (e.g., for safety-relevant restrictions in technical equipment) or cannot be modeled by costs in a sufficiently precise way. In such circumstances, one would rather insist on decisions guaranteeing feasibility “as much as possible”. This loose term refers once more to the fact that constraint violation can almost never be avoided because of unexpected extreme events. On the other hand, when knowing or approximating the distribution of the random parameter, it makes sense to call decisions feasible (in a stochastic meaning) whenever they are feasible with high probability, that is, only a low percentage of realizations of the random parameter leads to constraint violation under this fixed decision. A generic way to express such a *probabilistic* or *chance constraint* as an inequality is

$$P(h(x, \xi) \geq 0) \geq p. \quad (1)$$

Here, x and ξ are decision and random vectors respectively, and “ $h(x, \xi) \geq 0$ ” refers to a finite system of random inequalities and P is a probability measure. The value $p \in [0, 1]$ is called the probability level, and it is chosen by the decision maker in order to model the safety requirements. Sometimes, the probability level is strictly fixed from the very beginning (e.g., $p = 0.95, 0.99$ and so on). In other situations, the decision maker may have only a vague idea of a properly chosen level. Of course, he or she is aware that higher values of p lead to fewer feasible decisions x in Equation (1), and hence to optimal solutions at higher costs. Fortunately, it turns out that usually p can be increased over quite a wide range without affecting greatly the optimal value of some problem, until it closely approaches 1 and a strong increase in costs becomes evident. In this way, models with chance constraints can also give a hint for a good compromise between costs and safety.

Among the numerous applications of chance-constrained programming, one may find areas such as water resource management, energy production, medical and military science, circuit manufacturing, chemical engineering, telecommunications, reliability theory, and finance (for an overview see Ref. 1). For a comprehensive introduction into theory, models, and algorithms of probabilistically constrained programming we refer to Prékopa [2].

MODELS

Formally, the probabilistic constraint of Equation (1) can be understood as a single inequality

$$\alpha(x) \geq p,$$

where

$$\alpha(x) := P(h_j(x, \xi) \geq 0 \quad (j = 1, \dots, m)) \quad (2)$$

as it appears in optimization problems. However, it is by no means obvious to see how algorithmically important properties of α follow from those of the random constraint mapping h and of the distribution of ξ . The complicated interplay between these two ingredients gives rise to a variety of models leading to the application of different mathematical tools.

Joint and Individual Probabilistic Constraints

The probabilistic constraint as presented in Equations (1) or (2) is also called the *joint type* because it evaluates the probability of a whole random inequality system to hold true. Another possibility of treating the random inequalities would consist in transforming each one of them individually into a probabilistic constraint:

$$\alpha_j(x) := P(h_j(x, \xi) \geq 0) \geq p_j \quad (j = 1, \dots, m). \quad (3)$$

Here, it is possible to choose different probability levels p_j for each constraint. At first glance, the individual model looks more complicated than the joint one because the number of probabilistic constraints has increased now from 1 to m . It turns out, however, that in

certain situations one may benefit a lot from the individual character of the constraints in that they may avoid the consideration of multivariate random distributions as required for joint probabilistic constraints (see below). On the other hand, it is not this potential algorithmic simplification which should decide on the choice of joint or individual constraints but rather the right modeling point of view in a concrete application. As an illustration, one might think of a problem where the random vector represents a certain discrete stochastic process (e.g., some cash flow). With the individual model, a decision would be declared feasible whenever it guarantees, that at each individual time step some level has to be satisfied with a certain probability. In general, however, one is interested in satisfying this level with a given probability over the whole time horizon, which is a much more restrictive requirement. One can state the following relation between both types of constraint sets (where all probability levels are assumed to be equal in the individual model):

$$\overline{M}_p \supseteq M_p \supseteq \overline{M}_{1-(1-p)/m},$$

where

$$M_p := \{x | \mathbb{P}(h_j(x, \xi) \geq 0 \quad (j = 1, \dots, m)) \geq p\}$$

$$\overline{M}_p := \{x | \mathbb{P}(h_j(x, \xi) \geq 0) \geq p \quad (j = 1, \dots, m)\}.$$

In other words, each joint probabilistic constraint can be approximated from below and above by the corresponding set of individual probabilistic constraints upon adjusting the probability levels appropriately. This observation could be exploited in order to approximate programs with the more complicated joint constraints by solutions to programs with the simpler individual constraints. However, the gap between the lower and upper bound of the resulting optimal values can be large.

Random Right-Hand Side

Many practical applications (such as demand satisfaction) lead to probabilistic constraints with random right-hand side, hence $h(x, \xi) = g(x) - \xi$. The decoupling of decision

and random vector then allows rewriting of Equation (1) as

$$F_{\xi}(g(x)) \geq p, \quad (4)$$

where F_{ξ} refers to the (multivariate) distribution function of the random vector ξ . In this way, the generally nonexplicit mapping α in Equation (2) now gets a concrete shape as the composition $F_{\xi} \circ g$ of a distribution function and a fully explicit mapping of g . Though the computation of multivariate distribution function remains a challenging task, this setting offers far more efficient treatment than the general case. In particular, nondegenerate multivariate normal distributions are well investigated from the theoretical and algorithmic viewpoint [2–4]. For the computation of other multivariate distribution functions, such as gamma, Dirichlet, or exponential, we direct the reader to Refs 5–7.

The positive effect of the individual model (Eq. 3) for probabilistic constraints is revealed in combination with random right-hand sides. Indeed, one has the following equivalences for all $j = 1, \dots, m$:

$$\begin{aligned} \alpha_j(x) \geq p_j &\iff P(g_j(x) \geq \xi_j) \geq p_j \\ &\iff F_{\xi_j}(g_j(x)) \geq p_j \iff g_j(x) \geq q_{p_j}^{(j)}. \end{aligned} \quad (5)$$

Here, $q_{p_j}^{(j)}$ are the p_j -quantiles of the one-dimensional distribution functions F_{ξ_j} . Since quantiles of one-dimensional distribution functions are easily determined numerically, the individual probabilistic constraints on the left-hand side boil down to the right-hand side inequality system which is exactly of the same type as the original random inequality system $g_j(x) \geq \xi_j$. For instance, if g was a linear mapping, then the model of individual probabilistic constraints leads to linear inequalities again, which are easily incorporated into a linear programming problem.

Another situation in which advantage can be taken from a model with random right-hand side even for the more demanding case of joint probabilistic constraints as in Equation (2) is the following: if the random vector ξ has independent components, then

the calculation of α reduces to a product of one dimensional distribution:

$$\alpha(x) = F_{\xi_1}(g_1(x)) \cdots F_{\xi_m}(g_m(x)).$$

Although the constraint $\alpha(x) \geq p$ cannot be further simplified to an explicit constraint involving just the g_j (as it was the case for individual chance constraints), one may benefit again from the fact that one-dimensional distributions are easy to calculate.

Linear Probabilistic Constraints

As far as the structure of the mapping h in Equation (1) is concerned, the most typical case in practice occurs when h is affine linear in ξ in which case one speaks of linear chance constraints. There are two main situations to be distinguished then. The first and most important, h may be affine linear in the couple of variables (x, ξ) implying the probabilistic constraint (Eq. 1) takes the form

$$P(Ax + B\xi \geq c) \geq p, \quad (6)$$

where A, B, c are matrices/vectors of appropriate sizes. Typical applications of this model are reservoirs (water/money/energy etc.) with a discrete random inflow process ξ , the accumulation of which over time is described by means of B . A could similarly describe the accumulation of a discrete controlled outflow process but more generally A and B could also reflect network topologies in problems involving several reservoirs. Evidently, unless B is the identity, Equation (6) is not of the random right-hand-side type because ξ undergoes a linear transformation. Of course, one could formally put $\eta := B\xi$ such that the transformed random vector would yield the desired type. However, this is meaningful only if one knows how to also transform the associated distribution parameters. This is indeed possible when ξ obeys a multivariate normal or, more generally, an elliptically symmetric distribution. Therefore, for these distributions, Equation (6) can be considered to have random right-hand side. In particular, when passing from the joint model (Eq. 6) to the individual one in the sense of Equation (3),

then, as mentioned above, one arrives at a simple, explicit system of linear inequalities

$$\langle a_j, x \rangle \geq c_j + q_{p_j}^{(j)},$$

where the $q_{p_j}^{(j)}$ refer to the p_j -quantiles of the one-dimensional distribution functions of $\langle b_j, \xi \rangle$.

Coming back to the model with joint probabilistic constraints (Eq. 6), the following peculiarity is of interest: If B happens to be surjective and ξ follows a nondegenerate multivariate normal distribution, then so will the transformed random vector $B\xi$. In many applications, however, surjectivity of B can fail (e.g., when B describes demand satisfaction in the nodes of a network). Then, the normal distribution of $B\xi$ will be degenerate regardless of the nondegeneracy of the distribution of ξ .

The second instance of a linear probabilistic constraint allows a coupling of random and decision vectors while keeping affine linearity in ξ . The most prominent model is induced from a system of linear inequalities with random coefficient matrix:

$$P(\Xi x \geq c) \geq p. \quad (7)$$

Note that this probabilistic constraint is easily rewritten in our standard form (1) upon putting

$$h(x, \xi) := M(x)\xi - c; \quad \xi := \text{vec } \Xi;$$

$$M(x) := \begin{pmatrix} x^T & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & x^T \end{pmatrix},$$

where $\text{vec } \Xi$ refers to the row-wise vectorization of Ξ . Such models occur in problems where certain raw materials with uncertain concentrations are mixed (e.g., coffee blends or assets of a portfolio). Now, the coupling of x and ξ prevents a straightforward reduction of the probabilistic constraint (Eq. 7) to the case of random right-hand side. Nevertheless, it is still possible, for the aforementioned elliptically symmetric distributions, to rewrite Equation (7) in a form amenable to the calculus of multivariate distribution functions. To illustrate this in case ξ has a

normal distribution, assume that $\mathbb{E}\xi = \mu$ and $\text{Cov}(\xi, \xi) = \Sigma$. Then Σ is built up from blocks $\Sigma_{i,j} = \text{Cov}(\xi_i, \xi_j)$ (with ξ_i the i th row of Ξ) and one can easily show that

$$P(\Xi x \geq c) \geq p \iff F^{0, \Sigma(x)}(M(x)\mu - c) \geq p \quad (8)$$

Here, $F^{0, \Sigma(x)}$ refers to the distribution function of a multivariate normal distribution with zero mean vector and covariance matrix

$$\Sigma(x) = M(x)\Sigma M^T(x).$$

This means that for each fixed x the probability $P(\Xi x \geq c)$ can be calculated via the distribution function of a normal distribution, quite similar to what was the case for the random right-hand side model (Eq. 4). The difference to the latter consists in the fact that now the parameters of the distribution are not fixed but depend on x . This difficulty complicates the calculus of gradients to the probability function in the course of an optimization algorithm. Again, things simplify in a model with individual probabilistic constraints because—as a special case of the preceding observation—one has that

$$P(\langle \xi_i, x \rangle \geq c) \geq p_i \iff$$

$$F^{0, \sigma(x)}(\langle x, \mu_i \rangle - c_i) \geq p_i$$

$$(i = 1, \dots, m),$$

where now $F^{0, \sigma(x)}$ is the distribution function of the one-dimensional normal distribution with zero mean and variance $\sigma(x) = x^T \Sigma_{i,i} x$. Thanks to the one-dimensionality of the normal distribution, the usual standardization argument leads to the equivalence

$$P(\langle \xi_i, x \rangle \geq c) \geq p_i \iff$$

$$F^{0,1}(\sigma(x)^{-1/2}(\langle x, \mu_i \rangle - c_i)) \geq p_i$$

$$(i = 1, \dots, m),$$

where now the distribution function no longer depends on x . Passing to the quantiles q_{p_i} of the standard normal distribution, one arrives

again at a fully explicit description of the individual constraints:

$$\begin{aligned} P(\langle \xi_i, x \rangle \geq c) &\geq p_i \iff \\ q_{p_i} \sqrt{x^T \Sigma_{i,i} x} - \langle x, \mu_i \rangle + c_i &\leq 0 \\ (i = 1, \dots, m). \end{aligned} \quad (9)$$

This final form allows once more the passing of the individual probabilistic constraints directly to a nonlinear optimization solver.

Continuous and Discrete Distributions

In the models presented so far, only continuous distributions have been discussed.

The reason is that discrete distribution appears less favorable in the numerical treatment of probabilistic constraints than they are in expectation-based models of stochastic optimization. For instance, distribution functions of discrete distributions are discontinuous and lack concavity properties that may be hidden in continuous ones. Recent investigations, however, seem to justify an increasing interest in discrete distributions for solving probabilistically constrained programs. The key issue is finding the so-called p -efficient points [8] of the distribution function F_ξ of ξ . These are points z such that $F_\xi(z) \geq p$ and the relations $F_\xi(y) \geq p$, $y \leq z$ (partial order of vectors) imply that $y = z$. One easily observes that all the information about the p -level set of F_ξ is contained in these points because

$$\{y | F_\xi(y) \geq p\} = \bigcup_{z \in E} (z + \mathbb{R}_+^s),$$

where E is the set of p -efficient points and $\mathbb{R}_+^s$ is the positive orthant in the space of the random vector. In the case of ξ having integer-valued components and $p \in (0, 1)$, E is a finite set [Theorem 1 in Ref. 9]. Algorithms for enumerating or generating p -efficient points are described, for instance, in Refs 9 and 10.

STRUCTURAL PROPERTIES

In order to solve probabilistically constrained programs it is essential to know structural properties (e.g., continuity, differentiability,

concavity) of the function α defining the crucial inequality $\alpha(x) \geq p$ in Equation (2). The main challenge in establishing such properties consists in understanding the interaction between the random inequality system $h(x, \xi) \geq 0$ and the distribution of ξ . In simple cases, the effect is as expected. For instance, if the components h_i of h are upper semicontinuous (in both variables simultaneously), then α is upper semicontinuous as well and, as a consequence, the feasible set defined by the probabilistic constraint $\alpha(x) \geq p$ is closed, a minimum requirement in the context of optimization problems. This conclusion holds true regardless of any assumption about the distribution of ξ . Things become already much less obvious if (full) continuity is considered. Then, even the best distribution of ξ and the simplest type of h alone cannot guarantee the continuity of α . As an illustration, consider Equation (2), where ξ has a one-dimensional standard normal distribution and $h(x, \xi) = Qx + L\xi - b$ is affine linear with

$$(Q|L) = \left(\begin{array}{cc|c} 2 & 1 & -1 \\ -1 & 1 & 0 \end{array} \right); \quad b = \begin{pmatrix} 0 \\ -0.5 \end{pmatrix}.$$

Figure 1 shows the resulting probability function α which is evidently discontinuous.

It turns out that to the continuity of h one has to add the condition

$$\mathbb{P}(h_i(x, \xi) = 0) = 0 \quad \forall x \forall i,$$

which is violated in the example of the figure. Analogous unexpected phenomena occur in the characterization of Lipschitz continuity or differentiability of α which in the case of random right-hand side hinges upon the corresponding property of the distribution function F_ξ of ξ (4). For instance, it is obvious that for one-dimensional distribution functions Lipschitz continuity will follow from the boundedness of the underlying density, as soon as the latter exists. This conclusion does no longer hold true for dimensions larger than one. Then, it is not boundedness of the density itself but rather of the marginal densities which matters. On the other hand, the latter property can be easily verified for the class of so-called quasi-concave distributions. Similarly, the fact that

Figure 1. Example for a discontinuous probability function under smooth input data.

one-dimensional distribution functions are differentiable if they possess a continuous density does not carry over to larger dimensions. These difficulties are related with the calculus of improper integrals for densities with unbounded domain.

One of the most important features in numerical optimization is convexity of the set of feasible decisions. First of all, this is of interest in the case of random right-hand side (section titled “Random Right-Hand Side”). The question of convexity is very easy to answer if individual probabilistic constraints are considered. Given Equation (3), one has to check concavity of all the α_j (due to the inequality sign ‘ $\geq$ ’). Now, Equation (5) confirms that this concavity reduces to the concavity (or even just quasi-concavity) of the components g_j of g , which is easily checked as g is given explicitly. On the other hand, the individual model may be unjustified in many situations (see discussion in the section titled “Joint and Individual Probabilistic Constraints”). Things become more involved in the case of joint probabilistic constraints, because then convexity/concavity properties of multivariate distribution functions come into play. According to Equation (4), one would have to check concavity of the composition $F_\xi \circ g$.

Since distribution functions are increasing (with reference to the partial order), concavity of this composition would follow easily from concavity of the components g_j (which is easy to check) and from concavity of F_ξ . Unfortunately, being bounded from below and above but not constant, distribution functions are never concave (or convex). On the other hand, suitable transformations could do the job. For instance, upon passing in Equation (4) to the equivalent (by monotonicity of $\log$) inequality $\log F_\xi(g(x)) \geq p$, one realizes that concavity of $\log F_\xi$ would suffice. Checking log-concavity of F_ξ from the definitions is generally impossible due to a lack of explicit formulae for multivariate distribution functions. However, by a deep result due to Prékopa [11], log-concavity of distribution functions is equivalent with log-concavity of the underlying densities (if they exist). As one has typically access to explicit formulae for the densities, this offers a comfortable way to verify the desired property for the distribution functions. Given this, it turns out that a large class of multivariate distribution functions [including multivariate normal, Dirichlet, Gamma, uniform etc., refer [2]] shares the property of being log-concave. This allows us to apply convex optimization tools to

(joint) probabilistic constraints with random right-hand side whenever the random vector ξ has such distribution and the components g_j are concave (e.g., if g is an affine linear mapping).

The situation is again more complicated even for linear probabilistic constraints outside the setting of random right-hand side. Indeed for a probabilistic constraint of the type in Equation (7), no general convexity result is known even if ξ has a multivariate normal distribution. Again, individual probabilistic constraints are much easier to analyze. Indeed, having a look at Equation (9) and observing that $\sqrt{x^T \Sigma_{i,i} x}$ represents a norm, this inequality defines for arbitrarily fixed i a convex feasible set provided that $q_{p_i} \geq 0$ or, in other words, provided that $p_i \geq 0.5$. This observation is a classical result due to Van de Panne/Popp/Kataoka. As convex sets are stable under intersection, the whole system of inequalities (Eq. 9) is convex if $p_i \geq 0.5$ for all indices i . This restriction is not harmful because in probabilistic programming one is usually interested in probability levels close to 1. Generalizations to the case of joint probabilistic constraints of the type in Equation (7) are known up to now only for particular cases. For instance, when Ξ has a multivariate normal distribution and all rows of ξ are pairwise independent (whereas entries within each row may correlate) then the set of feasible decisions x defined by Equation (7) is convex for sufficiently large probability level p (12).

For a detailed analysis of convexity (in the individual model) and compactness (in the individual and joint model) of the feasible set defined by Equation (1) under elliptically symmetric distributions of ξ , we refer the reader to Ref. 13.

MONTE CARLO SIMULATION AS AN AID FOR DECIDING AMONG TREATMENT OPTIONS

STEVEN SHECHTER

Operations and Logistics Division,
Sauder School of Business,
University of British Columbia,
Vancouver, British Columbia,
Canada

Few decisions are as important and complex as choosing among treatment options. While randomized controlled trials (RCTs) are often considered the gold standard for deciding among treatment alternatives, they may be too expensive, risky, or time consuming to inform decision making in the near term. Yet decisions must go forward. And although physician experience is undoubtedly a key consideration, it is also important to synthesize available data into a critical analysis of the various options under consideration. This paper describes one increasingly popular technique for doing this, which contributes to the spirit of “evidence-based medicine:” Monte Carlo simulation (MCS) modeling.

The last two decades have seen significant increases in both computational power and the options available for treating various diseases. Though seemingly unrelated, these two evolutions have been wed over the years through the application of MCS modeling for evaluating treatment alternatives. By projecting the stochastic progression of a disease and the effects of various treatments over longer time periods, MCS models provide a useful methodology for evaluating and comparing treatment policies. For example, a MCS model has been used to evaluate the effects of different treatment start times for HIV patients [1]. Additionally, one may attach costs to the treatments and events that take place during the patient’s simulated lifetime, so as to evaluate the cost-effectiveness of the treatments alternatives. Examples include

the cost-effectiveness analysis (CEA) of HIV screening [2] and colorectal cancer screening [3]. The CEA that results by considering societal costs (and benefits) in these models is a useful tool for governments and insurers to decide which treatments should be covered and which should not. This is essential in an age of increasing health-care costs and limited health-care budgets.

Consistent with the recent focus on “patient-centered care” [4,5], MCS models may also be adapted to model the decision of a specific patient, rather than an “average” patient from a cohort. For example, some patients elicit different preferences for being in the same health conditions as well as different preferences for the value of time. MCS models can easily handle these considerations by incorporating patient-based utilities for being in various health states as well as discount rates for future outcomes. These often get summarized in one output measure used in the medical decision making literature for evaluating treatment benefits—quality-adjusted life years (QALYs) [6,7]. In other words, one treatment may result in a rather different estimate of QALYs for two different patients with the same health condition, due to their different valuations of quality of life. Moreover, if a particular patient’s disease progression does not seem characteristic of the cohort of patients upon whom the models were based (e.g., the patient under consideration may be a “rapid progressor”), the MCS model can be altered to reflect this and analyzed under that setting. The implication is that for some patients, a model may recommend one treatment while for other patients it may recommend a different treatment.

THE MONTE CARLO APPROACH

As disease progression is often a complex stochastic process, long-term patient outcomes are well suited to evaluation via simulation. These models work by using

(pseudo) random numbers to generate random changes to patient health (e.g., laboratory values or disease status) in a way that is consistent with a probability distribution representing the possible changes (for more on random number and random variable generation, we refer the reader to simulation textbooks such as Refs 8 and 9). These probability distributions, in turn, are based on available data and/or clinically reasonable assumptions. By simulating many sample paths of a patient's lifetime and then averaging outcomes, one may obtain estimates of several output measures of interest such as expected quality-adjusted lifetime and lifetime costs. As in traditional statistical sampling, the accuracy and precision of these estimates improves as more patient lifetimes are simulated.

Often, the underlying stochastic process is modeled as a discrete-time, discrete-state, Markov reward process [10–12]. For example, one might model monthly transitions between discrete health states (which may include categorized continuous variables) and accrue state-based benefits (e.g., quality-adjusted time in that health state) and/or costs over the patient's lifetime. Under restrictive assumptions (e.g., transition probabilities and rewards do not depend on time), one can apply matrix algebra to obtain the exact solution to a set of equations, which yield expected total outcomes. However, realistic models of lifetime patient outcomes must consider time-varying factors, such as age-based mortality rates. One way of dealing with this discussed in the medical decision making literature is referred to as the *Markov cohort simulation* approach [10,12], in which some arbitrary-sized cohort (e.g., 10,000 patients) is filtered at each time step according to the appropriate state transition probabilities, and members of each filtered subgroup accrue benefits and costs according to which state they moved. Because patient models have the absorbing death state, all patients get filtered to this state in the limit. The cohort simulation approach terminates when the number of patients still alive becomes sufficiently small, and then total rewards are tallied and divided by the original cohort

size. This approach is tantamount to working out the limit of a non-time-homogeneous Markov reward process, which does not have a straightforward matrix algebra solution as in the simple, time-homogeneous setting described before.

The other approach for evaluating outcomes discussed in the literature is MCS [10,12]: individual patients go one-by-one through the model, with each patient's state-trajectory until death determined by appropriate draws from the transition probabilities at each time period (e.g., patient health might be updated every month). Because of the probabilistic progression represented through these probabilities, two patients going through the model may have very different recorded outcomes (e.g., one simulated patient may die within a year, while another simulated patient with the same starting condition and disease dynamics may survive five more years). By running several patients through the simulation model and averaging results, the MCS approach provides an estimate of expected outcomes. The individual patient histories can also be used to understand other measures of the distribution of possible outcomes, such as variance, percentiles, and overall shape of the distribution (e.g., with a histogram). Moreover, by having a record of each patient's history, MCS allows for the easy calculation of several possible outcomes of interest, in addition to the expected lifetime calculation typically sought with the cohort simulation approach. For example, in a model of HIV treatment, one can use MCS to estimate the time until an AIDS-defining illness occurs, the time spent on different treatment regimens, or the probability of dying from HIV versus comorbid diseases [1]. Note that the MCS method is not exact: it provides a sample-based estimate, which itself is subject to variability (typically described through a confidence interval). However, this sampling variability vanishes to zero as the number of simulated patients approaches infinity, and by the law of large numbers, the sample mean converges to the distribution mean. We discuss statistical output analysis more below.

Besides allowing for a better understanding of the distribution of outcomes, MCS has other advantages that arise from its considerable flexibility. For example, it allows for easy consideration of transition probabilities that depend on patient histories (such as previous laboratory test readings, prior heart attacks, etc.). Technically, Markov models have state transitions that are independent of past history. While one can get around this by expanding the state definition to include some past history, this quickly expands the state space, making solution via matrix algebra or cohort simulation rather cumbersome. MCS is also very useful for establishing the face validity of a model: by observing generated patient histories, one can ascertain whether the model appears to be valid or not. For example, if a patient's simulated trajectory appears clinically implausible (or impossible), then the model should be refined to ensure that a similar trajectory cannot occur again.

Another advantage of MCS is that it no longer requires the traditional Markov process restrictions of discrete states and time steps. For example, one might use MCS to sample variability around a regression model [1] or a differential equations model [13] representing a continuous change in a patient variable over time, rather than break the variable down into arbitrary categories. Also, one might have an MCS model that allows a patient to remain in the same state for an amount of time that follows some distribution, rather than try to break that period of time up into smaller, discrete time periods. For example, in a model of end-stage liver disease and the effects of donated liver allocation policies, one might update patients' natural histories periodically in the model (e.g., monthly, so that one has up-to-date information in case an organ becomes available) [14], but then model the posttransplantation outcomes by just drawing the random time until either the patient's organ fails (and he/she needs to relist for a transplant), or the patient dies [15].

Even if a simple Markov process is used as a baseline model, many researchers will still apply MCS to conduct probabilistic sensitivity analyses (PSA) [16]. In general,

sensitivity analysis (SA) is an important step of model building: because one cannot be 100% certain of the accuracy of model inputs, SA allows one to understand how variation of the inputs affects variation of the outputs. The idea is that where outputs are sensitive to variation in inputs, one should collect more data to improve the accuracy of the inputs. While one may take a one-parameter-at-a-time approach to conducting SA, PSA considers simultaneous uncertainty (represented by a probability distribution over a range of values) across several parameters. As this is too complicated for exact analysis, MCS is used to estimate expected outcomes as well as proportions of the time that one treatment option yields better outcomes than the others.

Note that we distinguish MCS from traditional discrete-event simulation (DES) models, even though both use computer-generated random numbers to drive probabilistic outcomes. Our reason for doing so stems from the fact that simulation modeling is used widely in health care, and the applications typically fall into one of two types. The first is the patient-level disease modeling that we have described so far and refer to as MCS. The other applications involve models of health-care systems, in which patients join queues and compete for limited resources. A classic example is a simulation model of an emergency room, which considers the arrival pattern of patients, along with the available nurses, physicians, and beds, to estimate outcomes such as average patient wait time and resource utilization. For an overview of these and other similar types of process simulations in health care, we refer the reader to Ref. 17. These types of simulations are more traditionally referred to as *DES* (it should be noted, however, that some authors use "DES" in the way we use "MCS"). Common to both types of health-care simulations is a complex stochastic process which is not amenable to exact analytical solution, and for which a decision maker wants to evaluate various "what if" scenarios. In MCS, the stochastic processes are generally changes to patient health, while in DES, the uncertainty arises from randomness in patient arrival

times, service times (e.g., surgery duration), and resource availability (e.g., absenteeism and machine break down). The intended decision makers using MCS are patients, their physicians, and organizations tasked with deciding which treatments to pay for or not; users of DES are typically health-care managers and administrators in charge of the efficient operation of a health-care unit or system. Typically, MCS does not involve queueing: it assumes that the patient has access to whichever treatment is under consideration, and this is independent of other patients' path of care. However, some models do combine elements of MCS (the stochastic progression of patient health) with DES (patients competing for resources). For example, in the model of liver allocation described previously [15], MCS is used to stochastically evolve the health of patients waiting with end-stage liver disease, and DES is used to generate arrivals of patients and liver donations at random, discrete points in time. For a further discussion of modeling patient health progression within a DES framework, we refer the reader to Ref. 18.

STATISTICAL ANALYSIS OF SIMULATION OUTPUT

Randomness in inputs leads to randomness in outputs; therefore, a proper statistical analysis should be performed on an appropriate number of simulation replications. Whereas a replication in a DES model may represent what occurs at a clinic over the course of a day, a replication of an MCS model represents a particular patient's journey, from the starting conditions (e.g., age and state of disease) until death. Variability in disease progression and response to treatment may lead to different clinical events for different patients, resulting in different lifetimes, quality-adjusted lifetimes, and costs. MCS may be viewed as a computational method for sampling from an unknown distribution (e.g., the distribution of patient lifetimes under treatment A), and as with any statistical sample, we are interested in both point estimates of

outcomes of interest, as well as confidence intervals around these.

Suppose one wants to estimate the expected patient lifetime under a given treatment policy, with a 95% confidence interval half length of at most h years. A two-step heuristic for determining the appropriate number of patient replications is as follows: (i) run some moderately sized number, n_1 , of patients through the model, and find the sample standard deviation, s , of their lifetimes; (ii) run $n_2 = (1.96 \times s/h)^2 - n_1$ additional patients through the model and form the sample average and confidence interval for the $n_1 + n_2$ patient replications. If the resulting confidence interval is still not to the desired precision, then additional patients can be run through the model [9].

More commonly, the purpose of a MCS model is to compare patient outcomes under two or more different treatment policies. When comparing two treatment policies A and B, one can simulate n_A patients under A, n_B patients under B, and then perform an appropriate two-sample statistical analysis on the differences in outcomes between the two treatments. In fact, one can pair outputs from an identical number of replications of A and B and form the pair-wise differences, thus transforming the two-sample analysis into a standard one-sample analysis on the differences. This paired approach is especially useful when applying the variance reduction technique of common random numbers (CRN), which may yield similar precision in estimates but with many fewer replications (a discussion of CRN as applied to MCS is given in Refs 19 and 20). The idea behind CRN is that the random numbers used to generate events in the replication of one policy should also be used to generate events in the replication of another policy, so that one policy does not appear better than the other just because it received a more favorable stream of random numbers. For example, if the probability of death in a particular month under policy A is p_A and under policy B is p_B , then to simulate whether a patient dies that month under a given replication of A and B, the CRN approach would generate an instance of $u \sim \text{Uniform}[0,1]$, and if $u \leq p_A$, the patient

dies under policy A and if that same $u \leq p_B$, the patient dies under policy B. In other words, CRN avoids the replication giving a low Uniform[0,1] number to A but a higher one to B (which is more favorable to survival). The key to CRN is properly synchronizing the random number streams between policies so that they are used for similar purposes. Whereas this can be difficult to achieve for general DES models due to entities interacting with each other, MCS models are well suited to being able to achieve perfect or near-perfect synchronization, resulting in significant computational savings [19].

In comparing multiple treatment policies (say M), different perspectives may be taken. For example, if one policy is considered the status quo, then $M - 1$ confidence intervals may be generated (using the Bonferroni procedure), comparing the status quo policy to each other policy. If none is considered a baseline policy, then one can perform an all-pairwise comparison among the $M(M - 1)/2$ pairs. Ranking and selection procedures make statements about which policy is either the best or which subset of policies contains the best. For example, certain algorithms allow one to determine how many additional replications should be performed to be 95% confident that the policy with the best sample average is actually the one with the best true expected value. Other procedures allow one to determine how many of the top policies (according to the sample averages) should be included to achieve 95% confidence that the resulting subset contains the policy with the best expected value. This technique is sometimes performed as a first screening step to identify just a few of many policies as candidates for the best. For a further discussion of these methods, we refer the reader to Ref. 8.

CHOICE OF SOFTWARE

There are a wide variety of software options available for developing MCS models, ranging from general purpose languages (such as C or Java) to decision-analytic software packages with MCS capabilities (such as

TreeAge or Crystal Ball) to DES programs (such as Arena or Simul8). Modelers should spend time up front making a careful decision on software selection; otherwise, they may find that they have invested considerable time and money developing a model in one software language only to find that the model has become too complex to be adequately handled by that package. The choice of software may depend, among other things, on the following: (i) The degree of modeling flexibility one desires—general purpose languages having the most flexibility. (ii) The degree of computer programming experience one has—simulation-specific packages generally have nice graphical user interfaces which do not require programming expertise, as opposed to the line-by-line coding of general programming languages. (iii) Whether or not animation is important—animation is rarely used in MCS models of disease progression and treatment, but is often desired with DES models of patient flow through a system. DES packages have nice animation capabilities whereas, it is extremely burdensome to create an animation when working with a general programming language. (iv) Execution speed—for a given model, the run time of several patient replications will generally be much faster when executed from within a general programming language than from within a specialty simulation program. (v) Price—software products vary widely in the purchase cost, and this is where one would have to look into the features of each product, technical support, and so on, in making a decision.

CHALLENGES IN MONTE CARLO SIMULATION MODELING

Most of the challenges in MCS modeling center on the validation process. This is the means by which one gains confidence that the insights and conclusions of the modeling results would be similar to actual results if the same decisions were made in practice. Therefore, as with any modeling effort, the availability of useful data is essential. This may require prospectively collecting the data, obtaining retrospective data, or referring to

available literature (and perhaps combining published results into a meta-analysis). One should also be cognizant of what treatment policies were in place and whether they changed over the timeline of patients' longitudinal data, as this could affect the interpretation of patient health progression over time.

As mentioned above, having a clinician look at sample trajectories generated by the MCS to ascertain their plausibility is an important part of the validation process. After ensuring that the model does not generate any clinically absurd behavior, the validation process continues by comparing simulated output measures with available actual output measures. For example, one may compare the model with actual outcomes such as average lifetime, five-year survival probability, number of hospitalizations, time on therapy, and so on. Graphical and tabular comparisons are often used in these contexts. While traditional statistical hypothesis testing may be done to compare actual and simulated patient outcomes, one should keep in mind that a simulation model is necessarily an abstraction of reality; therefore, one should not strive to confirm a null hypothesis of equality of means, which is surely false [8]. In fact, with computer simulation, one can easily increase the number of patient replications to a point where the null hypothesis will be rejected. Instead, confidence intervals are more useful, as they shift the focus from whether there is a statistical significance of differences, to whether there is a clinically relevant difference between actual and simulated outcomes. Finally, SA is an important validation step, as it helps determine where more data should be collected or which assumptions should be carefully reexamined.

Time also presents validation challenges, in two different respects. First, a significant amount of time may pass from problem definition, to data collection and analysis, to model construction, and to model validation. Therefore, one should recheck that the model assumptions and data used near the beginning of the project timeline are still relevant near the end. Second, a key issue in

modeling long-term patient outcomes is the fact that medical research and development often leads to significant changes in the treatments available to patients over the course of their lifetimes. For example, in just the past 15 years, the standard for treating HIV has evolved from patients taking a single available drug (AZT) to them taking three different drugs (out of several available) simultaneously. This has led to dramatic improvements in patient survival. Therefore, an MCS model of HIV progression constructed just before new classes of antiretroviral drugs were developed (in 1995) would estimate radically different patient outcomes compared to a model constructed after this time. Because forecasting new treatment development is difficult at best, this remains a significant modeling challenge for the research community.

CONCLUSIONS

MCS takes advantage of computational power to estimate a variety of patient outcomes that may be too difficult to estimate otherwise. It should be viewed as one piece of a medical decision making process, rather than as a substitute for traditional clinical approaches to decision making. If randomized clinical trials are possible to run with a reduced set of treatment arms, then MCS provides a useful platform for narrowing down a multitude of potential treatment arms to consider in an RCT. If a clinical trial is simply not feasible to run, then an MCS model, in combination with clinical expertise and oversight, may recommend a best course of treatment for patients. Furthermore, one may incorporate costs into these models so as to determine the cost-effectiveness of the various treatment alternatives. That these models can impact policy recommendations is evidenced by a study that suggested it is cost-effective to screen nearly all adults for HIV, not just those at high risk for contracting the disease [2]. This influenced new CDC guidelines in 2006 that recommended routine screening for all people 13–64 years old [21]. Also,

MCS was recently used to support the development of new colorectal cancer screening guidelines in the United States [3,22].

FURTHER READING

In addition to all the references noted, we refer the reader to Ref. 23 for an overview of various modeling approaches to medical decision making. For a discussion of choosing one decision modeling approach over another, we refer the reader to Ref. 24. Recent developments in decision-analytic modeling in health care (including a discussion of patient simulation models), are discussed in Ref. 25. An annotated bibliography of simulation modeling in health care (covering both operational and medical decision making examples) is presented in Ref. 26. For more details on computer simulation in general, the reader is referred to various textbooks on this topic [8,9]. While these texts focus on traditional DES, they contain material that applies just as well to MCS (for example, detailed discussions of random number generation, validation, and statistical analysis).

MONTE CARLO SIMULATION FOR QUANTITATIVE HEALTH RISK ANALYSIS

ALISON CULLEN
Evans School of Public Affairs,
University of Washington,
Seattle, Washington

INTRODUCTION AND BACKGROUND

Managing risky opportunities, scenarios, and decisions is one of the most interesting and challenging aspects of human life. But meaningful characterization of risks is elusive because it relies on information that is incomplete, imperfect, and/or variable across time, space, and populations. And consequently informed decision making may be compromised. Probabilistic tools such as Monte Carlo simulation have evolved in which uncertainty and variability are characterized and carried through a process of generating probabilistic estimates of risk. The goal of this article is to introduce basic tools and techniques, as well as to provide pointers to other sections of this encyclopedia and some of the more common extensions practiced in the field. In order to preserve a focus, we restrict our treatment to the assessment of human health risk, while acknowledging that many other fields including finance, engineering, and law, can and do adapt these tools to a range of purposes extending far beyond those covered here. This article begins with an introduction to human health risk assessment. Following that introduction we explore the concepts of uncertainty and variability, the basics of Monte Carlo simulation, the sources of information used in this approach, probabilistic representation of risk model inputs, propagation of uncertainty and variability, and the identification of significant contributors to output variance.

The history of probabilistic risk assessment encompasses many fields of application including military decision making, engineering, medicine, and finance. These continue to be active fields of endeavor today. We find examples such as the use of random sampling techniques to solve challenging deterministic equations in the Manhattan Project at Los Alamos [1–3], applications in regulatory policy development such as the Reactor Safety Study with its eventual role in the development of probabilistic safety objectives for power plants [4] and the much contested application of value at risk models for financial risk management in which the unquantified tail risk accounts for a small but important fraction of the total risk [5]. In climate science, researchers confront output from a multimodel ensemble of atmosphere–ocean general circulation models and observations, introducing an overlay of model uncertainty, which joins the ever present uncertainty and variability, related to inputs such as future emission scenarios and climate sensitivity [6]. In medicine, we find cases in which interindividual differences between people throw into stark relief the distinction between clinical case management and epidemiological approaches to risk across populations [7], driven by the same concepts we confront in health risk analysis, our focus for this article.

Human health risk analysis produces estimates, ranges, and distributions related to the magnitude of adverse health effects resulting from man-made and naturally occurring health hazards. Decisions about how best to remove, reduce, or manage these risks are sometimes made by individuals on their own behalf. But these decisions are also made by regulators and other decision makers on behalf of subpopulations, large and small, aware and unaware, close to the source of risk or far removed from it. Decision making is complicated by limitations in our understanding of the physical, chemical, and

biological processes that mediate between hazards and people, limitations in the information and models available, and basic gaps in knowledge at every step of this chain, which result in our being uncertain about the magnitude and distribution of risk. Further complexity stems from the very real differences in exposure and sensitivity, which lead to very different likelihoods of negative health effects across populations, time, and space. These differences are referred to as *variability*.

More specifically, health risk is estimated as the product of exposure and dose/response factors and is expressed as the probability of a health outcome. The term *exposure* represents the level, duration, and frequency of human contact with an agent of risk and the route by which that contact occurs, for example, dermally, by inhalation, or by ingestion. Sources of exposure may be uncertain and/or exhibit variability over time, space, climate conditions and seasons, actions that mitigate or exacerbate the interaction of people and risk agents, and human behaviors and time activity patterns. Dose/response or exposure/response factors estimate the likelihood of a health outcome, that is, a response, given a specified degree of exposure. Dose/response relationships are uncertain and variable across individual populations, over genetic makeup, lifetimes, disease status, environmental triggers, and combinations of health threats. If major decisions are to be adequately supported, it is important to characterize and address both uncertainty and variability at an appropriate level [8–11].

TOOLS FOR ADDRESSING UNCERTAINTY AND VARIABILITY—SIMPLE TO COMPLEX

Addressing uncertainty and variability in a risk analysis takes many forms. At the simplest, it may refer to a qualitative discussion of data gaps and differences between human subpopulations or between different risk models themselves. Or it may refer to the acknowledgment of a basic and profound lack of insight into a future source of risk, a population at risk, or

the conditions under which the population and the risk source interact. These gaps can be handled by defining and running scenarios in which pivotal uncertainties are fixed with specific assumptions, and by multimodel analyses that grapple with model uncertainty by comparisons among model structures. Traditionally, when single values are assigned to risk model inputs they are selected to be protective of health, and in combination these can result in a “cascade of conservatism” far beyond the level of protectiveness that may have been intended originally [12,13]. At the other end of the spectrum, addressing uncertainty and variability, we find highly sophisticated and complex mathematical treatments based on statistical and/or artificial intelligence tools for estimating risk. Between these extremes, we find analytical methods exploiting mathematically exact solutions whose application rests on knowledge of the moments of the uncertain risk model inputs, and also numerical simulation methods such as Monte Carlo analysis, which rely on probabilistic descriptions and random number generators to carry uncertainty through the process. With the rise of desktop computing accompanied by vast leaps in computational power, speed, and ease, Monte Carlo methods have gained steadily in the field of risk analysis, while analytical solutions and approximations are increasingly rare for these applications. Detailed information about simulation approaches, in general, appears in the section titled “Simulation Modeling and Analysis”, with Monte Carlo Method appearing as the focus of the section titled “Monte Carlo Method” in this encyclopedia.

In order to justify the additional time, effort, or expense of extra layers of analysis it is necessary to consider the consequences of failing to pursue it. Where the cost of alternatives or post hoc remediation is high, there may be an argument for more sophisticated analysis. Likewise, where a rigorous comparison of options is needed, where the direction of additional scientific research will be decided, or where the stakes are potentially very high for any reason—it is easier to justify an additional focus on analysis.

MONTE CARLO SIMULATION FOR DEALING WITH UNCERTAINTY AND VARIABILITY

Monte Carlo simulation (and probabilistic analysis more generally) is neither the simplest nor the most complex approach to dealing with uncertainty and variability, as outlined at the beginning of this article. Its application has become very common in some areas of risk analysis, while it remains virtually nonexistent in others [14]. In very basic terms, *Monte Carlo simulation* refers to an approach in which probability and/or frequency distributions (histograms) are used to represent the components of risk models and are combined statistically to generate distributed estimates of risk. This is an alternative to deterministic approaches in which a single number is assigned to each input in a risk calculation, which is in turn carried out for a single context or scenario, resulting in a single number estimate of risk. By propagating representations of uncertainty and/or variability in inputs, assumptions, and decision contexts, through risk models, it is possible to generate a probabilistic description of risk which can open up a world of insight into related decisions.

While variability and uncertainty may be addressed with similar tools and techniques their roles in the decision process are markedly different. “Uncertainty forces decision makers to judge how probable it is that risks will be overestimated or underestimated for every member of the exposed population, whereas variability forces them to cope with the certainty that different individuals will be subjected to risks both above and below any reference point one chooses” [15]; see also Ref. 16. And the differences extend into the steps that follow analysis as well. Complex analysis and follow-up research have the potential to reduce uncertainty about an estimate of risk; however, more information is unlikely to reduce variability, since it reflects true and inherent differences over time, space, and individuals or populations. Further, most inputs that inform risk models carry both uncertainty and variability with them.

For example, the concentration of particulate matter in ambient air varies with location, averaging time, time of day, season and patterns of industrial, transportation, and individual behavior. The measurement of air pollution is an imperfect science; thus even with assumptions in place that fix all of the previously mentioned sources of variability exactly, we would still be uncertain about the concentration of particulate matter in ambient air due to instrument and analytic error, randomness, and other causes. To help distinguish the sources of variance that reflect true differences from those that reflect a lack of understanding, some analysts and decision makers prefer multidimensional analyses in which uncertainty and variability are represented in separate dimensions. These analyses result in multidimensional output, for example, probability surfaces rather than one-dimensional probability distributions of risk. For example, there may be variability in how much of a particular contaminant different individuals in the population are exposed to, as well as uncertainty about how dangerous the contaminant is to individual people who are exposed. Multidimensional analyses allow a simultaneous look at both of these aspects of risk and sometimes present opportunities to gauge whether uncertainty or variability is dominant in a particular instance.

Decision makers value analysis of both uncertainty and variability because it provides information that is useful for the communication, interpretation, or justification of a decision. It may provide a measure of the degree to which an estimate is conservative or a decision equitable. It may also reveal the relative impact of individual sources of uncertainty and variability on the decision at hand.

SOURCES OF INFORMATION—OBJECTIVE AND SUBJECTIVE

Sources of information for risk analyses include data, model results, expert judgment, and combinations of these. They span both objective and subjective categories as well. Perhaps not surprisingly there

is overlap between these; for example, judgment influences how, why, and what empirical data are collected, as well as how modeling efforts are approached and interpreted. Still it may be convenient to think in terms of objective and subjective information sources. And the development of probabilistic descriptions of model inputs necessarily depends on the nature, quantity, and quality of available information.

Where data exist it is possible to generate histograms representing past measurements. An example of this is the extensive database of measurements for factors such as fish consumption rates, time-activity patterns, and water ingestion rates published in the *Exposure Factors Handbook* [17]. Where insight into the processes that govern particular inputs is present, it is possible to develop probability distributions based on theoretical understanding. An example of this is the use of lognormal distributions to represent concentrations of environmental contaminants resulting from the knowledge that sequential dilution processes lead to lognormally distributed quantities [18,19].

Judgment in the form of expert elicitation is useful for generating distributions to represent quantities for which data exist but may be plagued by inherent systematic biases related to the timing, population, or conditions through which they were collected, for example, estimates of the increase in lung cancer associated with a $1\mu\text{g}/\text{m}^3$ increase in the concentration of fine particulate matter in air [20]. The elicitation of subjective probabilities and correcting for bias are the subject of articles *Eliciting Subjective Probabilities from Individuals and Reducing Biases*, *Eliciting Subjective Probability Distributions from Groups*, *Multivariate Elicitation: Association, Copulae, and Graphical Models*.

PROBABILISTIC REPRESENTATIONS OF UNCERTAINTY AND VARIABILITY

In Monte Carlo simulation, probability distributions link the possible values of a random variable, or ranges of possible values, with probabilities. A probability distribution

may be expressed as a probability density function (pdf) or a cumulative distribution function (cdf). For a continuous random variable, the area under a pdf represents the relative likelihood with which the specified range of values may be obtained. The cdf represents a cumulative total of the probability of occurrence of any value up to a specified magnitude of the random variable. For discrete random variables, the probability distribution function represents the probability of the random variable assuming any discrete value, for example, a histogram of historical measurements. For additional information about this area of probability and statistics the reader is referred to Hahn and Shapiro [21] or Benjamin and Cornell [22]. For examples of common distributional families and forms used in probabilistic human health risk analysis the reader is referred to Cullen and Frey [11].

We rarely have abundant, high quality, and relevant data for every quantity that goes into a risk model. For human health risk, inputs and models' absolute relevance would demand that the entire decision context and scenario of interest be reflected in the information used to represent inputs. This would encompass the averaging time, population demographics and characteristics, exposure scenario, season and climate, and other particulars. Obviously it is rare to have measurements that are perfectly relevant from one decision scenario to another. There are multiple means of addressing this lack of congruence between data sets and the needs of analysis. Sometimes it is possible to combine multiple data sets in order to develop a more generalizable distribution for a risk model input. At other times it is necessary to shift the first moment of an available input distribution, or to increase its variance using expert judgment, in order to reflect differences between the scenario in which the measurements were collected and the scenario or decision now at hand.

A more formal approach to combining multiple sources of information involves the use of Bayes' theorem to generate distributions, which reflect an expert analyst's belief or state of knowledge about an

uncertain quantity, or which combine the beliefs of multiple experts [23]. Aggregation of information from multiple experts is the subject of the section titled “Aggregating Individual Knowledge, Beliefs, and Preferences” in this encyclopedia. A particularly powerful application of Bayes’ theorem allows prior distributions based on subjective knowledge about model inputs to be refined or “updated” with information from other sources such as empirical measurements. In this process the relative impact of the empirical information will depend on how narrowly the prior describes the quantity, that is, how much certainty is reflected in the subjective statement of belief and certainty. With a broad prior distribution, implying a less informed analysis, even a small number of directly applicable measurements may have a huge impact on the resulting or posterior distribution. By contrast with a narrow prior distribution as the starting point, implying more certainty, one would need to mathematically incorporate many measurements demonstrating a high degree of consistency to have a noticeable impact on the shape of the posterior [24]. Further, Bayesian approaches may be applied to dealing with model uncertainty as in the context of multiple climate models mentioned earlier [6].

CORRELATION AND SIMULATION

Monte Carlo simulation has been criticized on occasion for assuming independence among model inputs. It is important to note that a tool does not assume anything; all assumptions in the analysis are made by a person (whether deliberately or not). Not surprisingly model inputs that come together in a risk model are often correlated among themselves. For example, individuals whose body weights fall in the low percentiles of the human body distribution are unlikely to have high percentile rates of food consumption. Monte Carlo simulation software tools are equipped to handle correlation between inputs. But, of course, this requires that analysts be aware of correlation and able to estimate its magnitude reasonably well. Also

the correlation must have the potential to significantly affect the results, so as to justify the effort of representing it. Smith *et al.* [25] studied the potential impact of neglecting correlations and present basic screening parameters to identify cases where it is important to treat these explicitly.

PROPAGATION OF UNCERTAINTY AND VARIABILITY

Numerical simulation techniques for propagating uncertainty and variability through models whose inputs have been defined probabilistically have been in use for decades. The most common technique is Monte Carlo analysis; however, this is just one of several related approaches including Latin hypercube simulation (LHS), importance sampling, and others. In Monte Carlo risk simulation a risk model is run repeatedly, each time with one possible value substituted for each uncertain or variable input. The value of risk associated with the specified set of input values is calculated and the output stored. This process is repeated 100, 1000, 10 000, or more times, while accumulating the output values, that is, the estimates of risk [10,21] (Fig. 1). The number of iterations may be selected based on the desired properties of the output distribution—such as stability of particular percentiles of interest—or dictated by resource constraints. The name Monte Carlo stems from the chance process by which the values of the uncertain and/or variable quantities are assigned for each run of the model. As with certain gambling games the values are random draws from the probability distributions representing each quantity. For simple Monte Carlo simulation the values are drawn randomly and according to the probability associated with each via the assigned probability distribution. As mentioned above, there are decision contexts in which the separate treatment of uncertainty and variability is warranted and valuable. The result then may take the form of a probability surface, rather than a one-dimensional distribution.

Many inputs to risk models are both uncertain and variable, although usually

one dimension or the other is dominant [11]. For two-dimensional analyses probability distributions may represent uncertainty across statistical descriptions of variability, such as those based on frequencies in random samples from a population. Kaplan and Garrick [26] defined risk as a triplet composed of scenarios, probabilities, and consequences. In health risk analysis, scenarios are defined such that variability inherent in biological, chemical, physical, and social systems is fixed. Probabilities are then employed to represent uncertainty. Consequences are outcomes, for example, potential health effects, costs, and so on. In developing two-dimensional input distributions, the parameters of the distribution of probability in one of the dimensions, such as that representing variability, are themselves distributed. This implies that both the mean and the variance of the distribution of the model input are also represented by distributions, according to the associated level of uncertainty. Variability and uncertainty are then propagated separately to produce two-dimensional output, in the form of a risk surface with variability in one dimension and uncertainty in the other [27].

Monte Carlo simulation relies on a random number generator to produce a set of random draws from a uniform distribution with bounds 0 and 1. These random draws

from the uniform distribution are then transformed to represent draws from other distributional families such as normals, lognormals, betas, and gammas. Most analysts rely on available software packages to achieve these steps and generate input values for the Monte Carlo simulation, for example, @Risk or Crystal Ball, which appear as overlays on spreadsheet programs on personal computers. In contrast with standard spreadsheets that can accommodate an individual number in a cell representing an input to a model, for example, body weight in an exposure calculation, these programs allow users to specify a distribution to represent each quantity by encoding the distribution parameters in the cell, for example, the geometric mean and geometric standard deviation defining a lognormal distribution of body weight. When an analyst launches a Monte Carlo simulation the software generates one random draw from each input distribution needed for the risk model, makes a deterministic calculation of risk dictated by this set of inputs, and then saves the result as one point in the output distribution. This process is repeated over and over until the desired number of points has been generated for the output distribution.

A common alternative to Monte Carlo simulation is LHS [28]. LHS addresses the

shortcoming of random draws taken from highly skewed or highly variable input distributions for the purpose of estimating risk. In these cases, a huge number of random draws would be required to ensure with any reasonable confidence that meaningful representation from the extremes or tails of input distributions had been achieved. LHS addresses this issue by using random draws from ranges of equal probability in the input distribution, rather than relying on simple random draws. Thus, LHS ensures that values from the whole range of each input distribution will be sampled, while still requiring that these draws be made according to the probability density as assigned. This stratified sampling approach, in some cases, increases the efficiency of sampling and reduces the number of iterations required in an analysis. However, it is worth noting that LHS does not always outperform Monte Carlo analysis, for example, when input-output relationships in risk models are nonadditive and/or nonmonotonically nonlinear [29]. LHS is an available option in most probabilistic simulation packages such as @Risk, Crystal Ball, and Analytica, with more sophisticated alternatives increasingly included as routine options in software as well.

The output distribution resulting from the Monte Carlo process, based on multiple individual calculations of risk, itself often becomes the subject of further statistical treatment. Although the output is generated by a simulation exercise, it may be analyzed with the same tools and techniques that would be applied to a data set of empirically or experimentally derived values. Analysis of the output distribution allows the analyst to determine percentiles of interest, especially upper end and lower end percentiles, which may be relevant to decision making. In addition, analysis of the output distribution is quite useful for identifying significant contributors to the overall variance in risk. For example, decisions about how to define the residential duration of local anglers used in assessments of polychlorinated biphenyls (PCB) exposure via fish consumption were shown to be highly significant in studies of communities living near the Hudson

river [30]. Finally, analyses of significant contributors to overall variance may take the form of value of information analysis, which serves as a precursor to planning directions for future research [23]. Value of information analysis is discussed in detail in the section titled "Value of Information and Option Values" in this encyclopedia.

Similarly, multidimensional output is well suited to additional interpretation through statistical analysis. For example, there may be specific percentiles of interest at the high or low end of the variability dimension. High end percentiles of variability often represent highly susceptible or highly exposed subpopulations. If output is two-dimensional the results carry additional information about uncertainty regarding specific subpopulations, represented by particular percentiles of variability. A detailed application from Cullen and Frey [11] related to community exposure to PCBs near a Superfund site illustrates one strength of this approach, gauging the relative importance of uncertainty and variability in exposure estimates. In this context they find that irreducible variability associated with interhousehold differences in exposure, such as lifestyle and diet choices, dominates variance in exposure estimates, as compared to measurement error, which is a function of the science, equipment, and laboratory techniques used in the measurement of contaminant concentrations.

IDENTIFYING SIGNIFICANT CONTRIBUTORS TO OUTPUT VARIABILITY

Analysts and decision makers often share a strong interest in identifying the most significant contributors to variability in a probabilistic risk assessment, even if they do not anticipate being able to do much to narrow the overall variance in the result. Their motivation to do sensitivity analysis is sometimes linked to the desire to know which uncertainties are driving the results, and consequently to gauge one's level of comfort with that knowledge. Alternatively, the sensitivity analysis may be cast as a comparison of alternative model structures to

measure the impact of making a particular selection on the decision at hand [31,33]. Inputs may be significant because of the way in which they enter the risk model, for example, as an exponent, or because of the degree of variance they exhibit themselves. In some cases it may be of more interest to identify inputs that have a strong influence on a particular percentile of the output distribution, for example, the 95th percentile. To get a sense of the likelihood of individual inputs to drive variance in the output before carrying out a simulation, analysts can look at the relative magnitudes of input variances or coefficients of variation, where models are composed of linear combinations of inputs.

After simulation, or where linearity does not hold, there are additional options. Analysts may look at scatter plots of individual inputs against the risk output; check the sample or rank correlation coefficient between a simulated input and the simulated output; or use techniques from multivariate linear regression including partial correlation coefficients, and rank regression coefficients [10,32]. A detailed development of sensitivity analysis methods is presented in the section titled "Communicating, Interpreting, and Understanding Decision Analysis Results" in this encyclopedia.

SUMMARY

Probabilistic simulation approaches for quantitative health risk analysis allow analysts and decision makers to be explicit about how they are addressing uncertainty. They allow a full and open exploration of the impact of decision about the treatment of uncertainty and variability on estimated distributions of risk across time, space, and populations. These tools also encourage a look into the future, with the consideration of options for additional data collection and future opportunities for developing alternative approaches for reducing risk. Finally, sound probabilistic simulation opens up the possibility for communication about

the limitations of results and any associated issues of generalizability.

MULTIARMED BANDITS AND GITTINS INDEX

RICHARD WEBER
Department of Industrial
Engineering, Universidad de
Chile, Santiago, Chile
Statistical Laboratory, University
of Cambridge, Cambridge, UK

THE MULTIARMED BANDIT PROBLEM

A multiarmed bandit is a slot-machine, or fruit-machine, with multiple arms. The arms differ in the distributions of rewards that they pay when pulled. An important special instance is when arm i is a so-called *Bernoulli bandit*, with parameter p_i . Such an arm pays \$1 with probability p_i , and \$0 with probability $1 - p_i$; this happens independently each time the arm is pulled. If there are n such arms, and a gambler knows the values of $p_1, \dots, p_n$, then he maximizes his expected reward by always pulling the arm of maximum p_i . However, if he does not know these parameters, then he must choose each successive arm that he pulls on the basis of the information he has obtained from previous pulls. His aim is to maximize some measure of the sequence of rewards he obtains.

Robbins Multiarmed Bandit Problem

Suppose that under some policy, the arm that is pulled on pull t is denoted i_t , and r_{i_t} denotes the reward obtained. In a version of the multiarmed bandit problem (MABP) due to Robbins [1], we define the *regret* after T pulls, as

$$\rho = T \max\{p_1, \dots, p_n\} - \sum_{t=1}^T r_{i_t},$$

and seek a strategy such that the average regret of ρ/T tends to 0 as T tends to infinity, for all values of the unknown parameters

$p_1, \dots, p_n$. This is possible with any sensible strategy that pulls each arm infinitely often, although some such policies are better than others in terms of minimizing a secondary criterion, such as the worst-case expected regret, $\sup_{p_1, \dots, p_n} E[\rho]$.

Gittins Multiarmed Bandit Problem

This article focuses upon a second formulation of the problem in which the aim is to maximize the expected total discounted reward over the infinite horizon

$$E \left[\sum_{t=1}^{\infty} r_{i_t} \beta^t \mid W_0 \right],$$

where β is a *discount parameter*, $0 < \beta \leq 1$, and W_0 is some initial information, such as prior distributions for the unknown parameters $p_1, \dots, p_n$.

Modeling generally, we formulate the MABP as a Markov decision problem in discrete time. Each arm i has a state $x_i(t)$, which is known at time t , ($t = 0, 1, 2, \dots$). The state of the decision problem is the vector of states $x(t) = (x_1(t), \dots, x_n(t))$. If at time t the gambler pulls arm i , then he obtains a reward of $r_i(x_i(t))$. The state of arm i moves to a new state y , with probability $P_i(x_i, y)$, where x and y are members of the state space of arm i , say E_i . The states of all other arms are unchanged and no rewards are obtained from them. In choosing which of the arms to pull at time t , the decision maker knows $x(t)$, and all the data of the problem; that is, he knows, for all i , the functions $r_i(\cdot)$ and $P_i(\cdot, \cdot)$. Given a discount parameter β , he wishes to maximize the expected discounted sum of rewards. Let π denote a policy, and let i_t denote the arm that is pulled at time t under this policy. In the language of Markov decision problems, we wish to find the value function

$$V(x) = \sup_{\pi} E \left[\sum_{t=0}^{\infty} r_{i_t}(x_{i_t}(t)) \beta^t \mid x(0) = x \right],$$

where the supremum is taken over all policies π that are realizable (or nonanticipatory), in the sense that i_t depends only on the problem data and $x(t)$, not on any information which can be known only after time t .

Setup in this way, the MABP is an infinite-horizon discounted-reward Markov decision problem. It therefore has a deterministic, stationary, Markov optimal policy. The natural way to address it is by its stochastic dynamic programming equation of

$$V(x) = \max_{i: i \in \{1, \dots, n\}} \left\{ r_i(x) + \beta \sum_{y \in E_i} P_i(x_i, y) \times V(x_1, \dots, x_{i-1}, y, x_{i+1}, \dots, x_n) \right\}. \quad (1)$$

In essence then, the MABP is about controlling the evolution of n independent reward-producing Markov processes. At each instant (in discrete time) exactly one of the processes is *continued* (and reward from it is obtained), while all the other processes are *frozen*. The continued process can change state, but the frozen processes do not change state. We suppose that reward is produced only from the continued process (although this assumption may be relaxed, as we see later.)

With respect to its usefulness in solving the MABP, Equation (1) suffers from the *curse of dimensionality*, which is typical in dynamic programming. Suppose, for example, that the state space of arm i is finite and of size $k_i = |E_i|$, $k_i \geq 2$. In principle, a solution to Equation (1) could be found by the policy improvement algorithm, or by solving a linear program. However, the vector state $x = (x_1, \dots, x_n)$ evolves on the state space $E = E_1 \times \dots \times E_n$, of size $k = |E| = \prod_i k_i$. So the number of stationary policies is n^k , where $k > 2^n$; also, the number of variables in a linear program would be $O(2^n)$. So the solution of Equation (1) is computationally infeasible even for moderate-sized k and n .

THE GITTINS INDEX

Remarkably, the MABP that has been described above can be solved by an *index policy*. That is, we can compute a number

(called an *index*), separately for each arm, such that the optimal policy is always to pull the arm having the currently greatest index. As an introduction, we illustrate the idea of an index policy with an example from job scheduling.

Single Machine Scheduling. Suppose that n jobs are to be processed successively on one machine. Job i has a known processing times t_i , assumed to be a positive integer. On completion of job i , a positive reward r_i is obtained. If job 1 is processed first, and job 2 is processed immediately after it, then the sum of discounted rewards obtained from these two jobs is $r_1\beta^{t_1} + r_2\beta^{t_1+t_2}$. If the processing order of the jobs is interchanged, we obtain $r_2\beta^{t_2} + r_1\beta^{t_1+t_2}$. A little algebra shows that the first ordering has the greater reward if $r_1\beta^{t_1}/(1 - \beta^{t_1}) > r_2\beta^{t_2}/(1 - \beta^{t_2})$. Using this idea, it is not hard to see that the total discounted reward obtained from the n jobs is maximized by processing them in decreasing order of indices, computed as $v_i = r_i\beta^{t_i}/(1 - \beta^{t_i})$.

The appropriate index for the MABP is in the same spirit, but more complicated. The key result for the MABP is the following.

Gittins Index Theorem. *The multiarmed bandit problem, as setup above, is solved by always pulling the arm having the greatest Gittins index, which is defined for arm i as*

$$G_i(x_i) = \sup_{\tau} \frac{E \left[\sum_{t=0}^{\tau-1} \beta^t r_i(x_i(t)) \mid x_i(0) = x_i \right]}{E \left[\sum_{t=0}^{\tau-1} \beta^t \mid x_i(0) = x_i \right]}, \quad (2)$$

where τ is a stopping time constrained to take a value in the set $\{1, 2, \dots\}$.

By a “stopping time” τ we mean a time that can be recognized when it occurs. In fact, it can be shown that τ attains the supremum when $\tau = \min\{t : G_i(x_i(t)) \leq G_i(x_i(0)), \tau > 0\}$; that is, τ is the first time at which the process reaches a state in which the Gittins index is no greater than it was initially.

Examining Equation (2), we see that the Gittins index is the maximal possible

quotient of a numerator that is “expected total discounted *reward* over τ steps,” and denominator that is “expected total discounted *time* over τ steps,” where τ is at least one step. Notice that the Gittins index can be computed for all states of arm i as a function only of the data $r_i(\cdot)$ and $P_i(\cdot, \cdot)$. That is, it can be computed without knowing anything about the other arms. The curse of dimensionality disappears. If arm i moves on a finite state space of size k_i , then its Gittins indices (one for each of the k_i states) can be computed in time $O(k_i^3)$ [2,3].

In the job scheduling example just considered, the optimal stopping time on the right-hand side of Equation (2) is $\tau = t_i$, the numerator is $r_i \beta^{t_i}$ and the denominator is $1 + \beta + \dots + \beta^{t_i-1} = (1 - \beta^{t_i})/(1 - \beta)$. Thus, $G_i = r_i \beta^{t_i} (1 - \beta)/(1 - \beta^{t_i}) = (1 - \beta) v_i$.

The index theorem above is due to Gittins and Jones, who had obtained it by 1970, and presented it in 1972 [4]. They called $G_i(x_i)$ a *dynamic allocation index*, but it is now widely known as the Gittins index. The result became better known with Gittins’ paper of 1979 [5]. The idea that an optimal policy might have an index characterization was not new, since it had been known for some very simple scheduling problems since the 1950s [6]. In the 1970s, a deeper understanding of the optimality of index policies for more complicated problems was advancing rapidly. Researchers such as Klimov [7], Sevcik [8], Harrison [9], Tcha and Pliska [10], and Meilijson and Weiss [11] were proving results about the optimality of index policies for scheduling problems in various forms of multiclass queues, and finding indices similar to Gittins indices.

Nonetheless, the solution of the MABP in the general setting that has been described above impressed many experts as surprising and beautiful. In the forward to Gittins’ book [12], Whittle describes a colleague of high repute, asking another colleague “What would you say if you were told that the multi-armed bandit problem had been solved?” The reply was “Sir, the multi-armed bandit problem is not of such a nature that it can be solved.”

Subsequent to Gittins’ pioneering work, many researchers have sought to reprove

the index theorem by different means, to exploit it and to understand how it might be generalized. Today, the multiarmed bandit model and Gittins indices are widely used by researchers in computer science, economics, engineering, operations research, and statistics. Let us make some brief notes on other characterizations of the Gittins index and its associated policy.

Calibration. An alternative characterization of $G_i(x_i)$ is

$$G_i(x_i) = \sup \left\{ g : \frac{g}{1 - \beta} \leq \sup_{\tau > 0} E \left[\sum_{t=0}^{\tau-1} \beta^t r_i(x_i(t)) + \beta^\tau \frac{g}{1 - \beta} \mid x_i(0) = x_i \right] \right\}.$$

That is, we may consider a two-armed bandit problem that is posed for arm i and one other *calibrating* arm which pays out a known reward g at each pull. The Gittins index of arm i is the value of g for which it is optimal to pull either arm initially. Notice that once we decide to switch from pulling arm i to pulling the known arm, at time τ , then information about arm i does not change and so it would be optimal to stick with pulling the known arm ever after.

Forwards Induction. If we put $\tau = 1$ on the right-hand side of Equation (2), then it evaluates to $E r_i(x_i(t))$. If we use this as an index for choosing between projects, we have what is called a *myopic* or *one-step-look-ahead* policy. We may view the Gittins index policy as generalizing the idea of a one-step-look-ahead policy, since it looks-ahead by some optimal time τ , so as to maximize, on the right-hand side of Equation (2), a measure of the rate at which reward can be accrued. This defines a so-called *forwards induction policy*. Similarly, one can define a forwards induction policy for any Markov decision process. Either the one-step-look-ahead-policy or a forwards induction policy needs to be optimal, but they can provide guidance about heuristics.

Proofs of Optimality

Alternative proofs of the Gittins index theorem have helped to reveal its beauty and initiate further developments; for example, for heuristic approaches to problems that do not quite fit the assumptions of the MABP. We mention four proof methodologies: (i) interchange arguments [2,4,13–15], (ii) a linear program posed over an achievable region for a performance measure [16], (iii) an explicit formula for the value function that can be shown to satisfy the dynamic programming equation [17], and (iv) an intuitive method based on the notion of a “fair charge” [18]. We sketch the main ideas of (i)–(iii), and essentially the full proof of (iv).

The idea of an “interchange argument,” mentioned as (i), has already been illustrated in the single machine scheduling problem described above. However, great care is needed to make an interchange argument work for the MABP. In particular, one has to find a clever way to interchange τ_1 successive pulls of arm 1 followed with τ_2 successive pulls of arm 2, choosing τ_1 and τ_2 to be special stopping times.

Method (ii) recasts the MABP as a linear program. One defines z_{ij} as the expected total discounted total time spent pulling arm i on occasions that it is in state j . The MABP can be formulated as a linear program in variables z_{ij} , with objective function of $\sum_i \sum_{j \in E_i} r_i(j) z_{ij}$, and subject to certain constraints on the z_{ij} . For instance, since one arm must be pulled at each time, one of these constraints is $\sum_{i=1}^n \sum_{j \in E_i} z_{ij} = 1 + \beta + \beta^2 + \dots = 1/(1 - \beta)$. It turns out that the resulting special linear program can be solved by computing its optimal dual variables by way of a greedy algorithm, which also calculates the Gittins index values. This proof method resonates with work of Klimov [7], in which essentially the same greedy algorithm is used to compute indices for an index policy. The greedy algorithm works because the achievable region is an *extended polymatroid* [16].

In method (iii) the standard setup is augmented by giving the decision maker a *resignation option*, such that he may any time choose to take a lump sum M , and then pull

no further arms. Let $V(x, M)$ be the value function in this augmented problem when $x = (x_1, \dots, x_n)$ is the initial vector of states of the arms. Suppose that there is an upper bound R on the value of the total discounted reward, and M is such that resignation in a finite time is certain. By demonstrating that it solves the relevant dynamic programming equation, Whittle [17] showed that $V(x, M)$ can be expressed as

$$V(x, M) = R - \int_M^R \prod_i \frac{\partial \phi_i(x_i, m)}{\partial m},$$

where $\phi_i(x_i, m)$ is the maximal expected discounted reward in the one-armed bandit problem of arm i on its own, initially in state x_i , and augmented with the resignation option.

Finally, we turn to (iv) and present a proof in the following few sentences. Consider a one-armed bandit problem in which only arm i is available. Let us define the “fair charge,” $\phi_i(x_i)$, as the maximum amount that a gambler would be willing to pay for each further pull of arm i in order to be permitted to pull it at least one more time, but then being free to quit whenever he likes after the first pull. We next define the “prevailing charge” for arm i at time t as $g_i(t) = \min_{s \leq t} \phi_i(x_i(s))$. So $g_i(t)$ actually depends on $x_i(0), \dots, x_i(t)$ (which we omit from its argument for convenience). Note that $g_i(t)$ is a nonincreasing function of t and its value depends only on the states through which arm i evolves. The proof of the index theorem is completed by verifying the following facts, each of which is almost immediate. (i) If, in the MABP with n available arms, the gambler not only collects rewards but also must pay the prevailing charge of each arm as he pulls it, then he cannot do better than break even (in terms of expected value). (ii) He maximizes the expected discounted sum of the prevailing charges that he pays by always playing the arm with the greatest prevailing charge. (iii) Using this strategy he also breaks even; so this strategy, of pulling an arm having greatest $g_i(x_i)$, maximizes the expected discounted sum of the rewards he can obtain from the arms. By simple algebra, one can check that $g_i(x_i) = G_i(x_i)$.

Calculation of the Gittins Index

We now turn to the problem of computing the Gittins index value for each possible state of a given arm i . The input to this calculation is the data for arm i of $r_i(\cdot)$ and $P_i(\cdot, \cdot)$. If the state space of an arm i is finite, say $E_i = \{1, \dots, k_i\}$, then the Gittins indices can be computed in an iterative fashion. First, we find the state of greatest index, say 1 such that $1 = \arg \max_j r_i(j)$. Having found this state, we can next find the state of second-greatest index. If this is state j , then $G_i(j)$ is computed in Equation (2) by taking τ to be the first time that the state is not 1. This means that the second-best state is the state j , which maximizes

$$\frac{E[r_i(j) + \beta r_i(1) + \dots + \beta^{\tau-1} r_i(1)]}{E[1 + \beta + \dots + \beta^{\tau-1}]},$$

where τ is the time at which, having started at $x_i(0) = j$, we have $x_i(\tau) \neq 1$. One can continue in this manner, successively finding states and their Gittins indices, in decreasing order of their indices [2,15]. This method is foreshadowed in the way Klimov calculated indices for his problem [7], and the greedy algorithm in Bertsimas and Niño Mora [16] is similar. For further ways of calculating indices see also Niño Mora [3], Katehakis and Veinott [19], and Sonin [20].

If the state space of an arm is infinite, as in the case of the Bernoulli bandit, there may be no finite calculation by which to determine the Gittins indices for all states. In this circumstance, we can approximate the Gittins index using something like the value iteration algorithm. Essentially, one solves a problem of maximizing right-hand side of Equation (2), subject to $\tau \leq N$, where N is large.

APPLICATIONS

Clinical Trials

The MABP has its history in a model of clinical trials in which a decision maker is trying to discover which of n drugs has the greatest probability of providing successful treatment. As explained in the beginning of this article, there is an unknown

probability p_i with which drug i successfully treats a patient, where p_i has some known prior distribution. The posterior distribution of p_i is updated as independent observations of successes and failures of the drug are observed. For example, if the prior distribution of p_i is uniform on $[0, 1]$ and s successes and f failures are observed, then the posterior distribution of p_i is a beta distribution, with density proportional to $p^s(1-p)^f$, $0 \leq p \leq 1$.

Patients are treated one at a time. The decision maker knows the number of successes and failures that has been observed for each drug so far. He must choose a drug with which to treat the next patient. In the short term, if he cared only about the next patient, he would use the drug that has the greatest success probability. This is one for which the posterior mean is greatest, this being $(s_i + 1)/(s_i + f_i + 2)$. This is the *myopic policy*, which places all emphasis on exploitation. However, an optimal policy must also pay attention to exploration.

It is instructive to look at some numbers. Suppose that in 8 treatments with drug i we have seen 4 successes and 4 failures, and that in 40 treatments with drug j we have seen 20 successes and 20 failures. Then the posterior means of p_i and p_j are both 0.5. From the tables in Gittins [12] given for $\beta = 0.8$, we read that the Gittins indices for drugs i and j are 0.5431 and 0.5114, respectively. This means that if we were faced with a two-armed bandit problem consisting of just drugs i and j , then we would strictly prefer the next treatment to be with drug i , even though the posterior means of p_i and p_j are the same. This is because there is more to be learned by experimentation with drug i than with j . Similarly, if we are faced with a two-armed bandit problem consisting of drug i and one other drug k , which has known success probability p_k , then we should strictly prefer to make the next treatment with drug i if $p_k < 0.5431$. The fact that the Gittins index exceeds 0.5, reflects the fact that there is potential to learn that $p_i > 0.5$. If $\beta = 0.9$ then the Gittins index for drug i is 0.5676. This is greater than its value for $\beta = 0.8$, since future rewards count more as β becomes closer to 1.

As we have already noted, the fact that the state space of a Bernoulli bandit is infinite means that there is no method of calculating the Gittins indices exactly. The tables in Gittins [12] were produced by a method of approximation in which the stopping time τ in Equation (2) was constrained to be no more than N , with $N = 300$ being found sufficient to estimate the indices to four significant figures.

It is worth remarking that an elementary version of this problem was solved by Bellman [21], for the special case in which there are just two drugs and the success probability of one of them is known, and by Bradt *et al.* [22] for undiscounted rewards and a finite horizon. These authors elucidated indices characterizing optimal policies (but without actually calling them indices). They presaged the idea, described above, in which an arm with unknown p_i is calibrated against an arm with known p_k such that one is indifferent (in a two-armed bandit problem) as regards initially pulling arm i or k .

Target Processes

The Gittins index can also be used to solve a problem in which the objective is to minimize costs up until the first time that one of the arms pays out a jackpot. An example is the game of “golf with n balls,” described in Dumitriu *et al.* [23]. Imagine a golfer is playing with n balls, each of which rests in a different location. The golfer is to play one ball at a time (incurring cost as he does so, and with a known probability distributions determining how balls move). His objective is to minimize the expected cost incurred until he first puts one of the balls into the hole. We can make this a standard MABP by imagining that once a ball goes in the hole it is in a state that it can be played with 0 cost thereafter. So the Gittins index theory can answer the question: Which ball should the golfer hit next?

More practically, a company might be engaged in pharmaceutical research and wishing to discover a drug that achieves a target level of effectiveness, T . Suppose that there are n families of similar compounds. On successive trials of compounds from family i , the observed effectiveness is

$X_i(1), X_i(2), \dots$, where these are independent and identically distributed according to an exponential distribution with parameter θ_i . The value of θ_i is unknown, but *a priori* it is exponentially distributed with known mean μ_i . It is desired to minimize the expected number of trials until first obtaining a reward that exceeds T . Thus, after having made a first observation $x_i = X_i(1)$, the posterior distribution of θ_i is proportional to $x_i \exp(-x_i \theta_i) \mu_i \exp(-\mu_i \theta_i)$. See Gittins [12] for more details, and tables of index values for such problems.

Job Scheduling

The theory of MABP and the Gittins index theorem for discrete-time Markov reward processes can be extended to bandits which evolve in continuous-time as semi-Markov processes. A continuous-time setting is more appropriate when we wish to model the processing of jobs.

Suppose we are given n jobs, and that job i has an unknown processing time, which may be modeled as a random variable with distribution function F_i and density f_i . The only reward that can be obtained from a job i is obtained upon its completion, and this is r_i . We wish to maximize the expected sum of discounted rewards obtained by processing the jobs on a single machine. It turns out that if job i has been processed for time x_i and has not yet completed, then its Gittins index at that point is

$$G_i(x_i) = \sup_{\tau > 0} \frac{r_i \int_0^\tau e^{-\gamma t} f_i(x_i + t) dt}{\int_0^\tau e^{-\gamma t} [1 - F_i(x_i + t)] dt}, \quad (3)$$

where $e^{-\gamma t}$ ($\gamma > 0$) plays an analogous role to β^t .

In some special cases, Equation (3) is easy to evaluate. The *completion rate* of job i (which is also called the hazard rate or failure rate) is defined as $\rho_i(x) = f_i(x)/(1 - F_i(x))$. This has the interpretation that if having been processed for time x the job is not yet complete, then $\rho(x)\delta + o(\delta)$ is the probability that it does complete when given a further small amount of processing δ . If the processing times of all jobs have

completion rates that are decreasing in x , then $G_i(x_i) = r_i \rho_i(x_i)$, so it is optimal to always process the job of greatest value of $r_i \rho_i(x_i)$, where x_i is the amount of processing job i has received thus far. Similarly, if all jobs have increasing completion rates, then the optimal τ in Equation (3) is ∞ . In this case, as $\gamma \rightarrow 0$, we find $G_i(x_i) \rightarrow r_i/E(\text{remaining processing time} | x_i)$.

Tax Problems

In a variation of the job scheduling problem, one is charged a tax (or holding cost) c_i , so long as job i is not complete. If the job were never to be completed, then the total discounted cost so paid would be $\int_0^\infty c_i e^{-\gamma t} dt = c_i/\gamma$. So an alternative way to compute the true expected total holding cost is to imagine that we must pay c_i/γ at time 0 for every job, but then receive a “refund” as reward $r_i = c_i/\gamma$ at the time when job i completes. Thus, tax problems can be solved as MABPs. By a similar construction, one can generalize the standard MABP by permitting state-dependent rewards to be obtained from frozen arms. See the work of Varaiya *et al.* [15], who also describe an algorithm for computing indices, similar to Tsitsiklis [2].

If $\mu_i = 1/E(\text{remaining processing time} | x_i = 0)$ (as is the case when job i has a processing time that is exponentially distributed with parameter μ_i) then as $\gamma \rightarrow 0$, we find $G_i(x_i) \rightarrow c_i \mu_i$, the famous so-called ‘ $c\mu$ rule’. Cost is minimized by allocating the processing to the job of greatest value of $c_i \mu_i$.

Much more could be said about how the theory of the Gittins index can be used to solve scheduling and stochastic scheduling problems. It can be used to prove that a $c\mu$ rule provides optimal for scheduling in a multiclass $M/G/1$ queue. An idea of “arm-acquiring bandits” can be used to give a solution to Klimov’s problem about scheduling in such a queue when there is also Markovian feedback [7]. The theory is also useful in discussing stochastic scheduling problems in which there are precedence constraints between jobs, and in evaluating the suboptimality of index policies with switching costs [24,25]. For more on scheduling and stochastic scheduling problems see Pinedo [26].

GENERALIZATIONS

The Gittins index provides the solution to the MABP, under the modeling assumptions posed for it above. However, an index policy is not optimal, in general, if any of the following are true: (i) the time horizon is finite rather than infinite, (ii) the discount rate depends on the arm that is pulled, or (iii) more than one arm can be pulled at the same time.

There is one interesting example of a stochastic job scheduling problem in which an index policy is optimal in the case of (iii). Suppose n jobs have unknown processing times which are *a priori* distributed independently as exponential random variables with known parameters $\lambda_1, \dots, \lambda_n$. The jobs are to be processed using $m (\geq 2)$ identical machines operating in parallel. Then the expected flow sum of completion times (called the flow time) is minimized by giving priority to short jobs (largest λ_i), and the expected completion time of the last job (called the makespan) is minimized by giving priority to long jobs (smallest λ_i). This can be generalized to some other distributions [27]. However, such a result is exceptional. Most problems that include aspects of (i), (ii), or (iii) are NP-hard.

Restless Bandits

A restless bandit is a generalization of a one-armed bandit, in which we relax the assumption that the state of an arm is frozen when it is not pulled. We suppose that there are two controls, called “active” and “passive,” which can be applied to each arm. The rewards and state evolution differ under the active and passive controls. This model has proved popular in a number of application areas, where typically active/passive controls can correspond to running a system fast/slow, or monitored/unmonitored, or to workers being in states of laboring/resting.

The restless bandits model is due to Whittle [28], who suggested a heuristic index policy for the multiarmed restless bandit problem that can be described as follows. Consider a one-armed restless bandit and imagine that we provide a subsidy λ each time that a bandit in the passive state is pulled. Taking our objective to be the maximization of time-average reward obtained

from this one restless bandit, it is reasonable to imagine that as λ increases from $-\infty$ to ∞ the set of states in which it is optimal to take the passive action increases monotonically, from the empty set to the set of all states.

If this monotonicity in λ holds for bandit i (said to be indexable), then in state x_i , we can define the index $W_i(x_i)$ as the value of λ such that one is indifferent between applying the passive and active controls in state x_i . As with the Gittins index, this “Whittle index” for bandit i is a function only of the data for bandit i . If the objective is to maximize time-average reward under a constraint that the active control be applied to exactly m ($< n$) of the arms at each instant, then a heuristic is to apply the active control to the m bandits of greatest $W_i(x_i)$. In the case that $m = 1$ and the passive control is the same as freezing, then this is the same as the Gittins index policy. If $m > 1$ and the passive action is not freezing, then the Whittle index policy may not be optimal, but many researchers find that the heuristic works well [29].

MULTICLASS QUEUEING NETWORK MODELS

JOHN J. HASENBEIN
Department of Mechanical
Engineering, University of Texas
at Austin, Austin, Texas

INTRODUCTION

A multiclass queueing model is a network with a number of stations, each of which process multiple classes of customers. These networks are a generalization of the classic queueing network models of Jackson and Kelly, among others. In this section, we give an informal description of these models and a more formal mathematical description is presented in the next section. To begin, suppose the network consists of J processing stations. Each station could have multiple identical servers, but for simplicity, we focus on the case in which each station consists of a single server with an unlimited buffer for customers waiting to be processed at the station. Customers in the network are partitioned into K classes, with each class being associated with a fixed station. Customers within a class are homogeneous in terms of their processing requirements and routing requirements, after service. In particular, the service requirements for customers at a station are determined only by the class of the customer. A simple special case is when the service times for customers of class ℓ form a sequence of i.i.d. random variables. Furthermore, although customers can be routed in a random manner after service at a station, all customers of class ℓ are routed using the same mechanism after they complete their processing at the station associated with that class. We assume that customers of type ℓ arrive exogenously according to some counting process, are routed through the network for processing, and then depart the network. The discussion focuses on the case when

all customers depart eventually with probability 1 (w.p. 1). Such networks are called *open*. When $J = K$ the network is a single-class network, that is, all customers waiting for service at a given station are homogeneous. When $K > J$ at least one station serves more than one class of customers, thus giving rise to the term *multiclass*. In summary, we describe here *open multiclass queueing networks* (OMQNs) with single-server stations. Generalizations to this model are mentioned in the section titled “Further Topics”, but the most important features of this class of networks are contained in the model described in this article.

Perhaps, the best way to see the utility of OMQN models is to compare them to the classic open Jackson network described in the article ***Jackson Networks (Open and Closed)***. The OMQN extends Jackson’s model in a number of ways. First, in a Jackson network, service and interarrival distributions are exponential. In an OMQN, this restriction is removed. Second, in a Jackson network, all customers at a station have homogeneous service and routing requirements, whereas this need not be true in an OMQN.

In a Jackson network, the routing requirement is perhaps more restrictive than it initially appears. To see this, consider a simple network with two stations, A and B. Every customer needs to undergo service at station A, then station B, and the station A, after which it departs the system. Any network with this routing mechanism is not a Jackson network because the customers at station A are not homogeneous with respect to their routing. In particular, after service at station A, some customers will go to station B and some will depart the system, depending on whether or not the customer has undergone an earlier service at station A. Therefore, many relatively simple networks with exponential service and interarrival times are outside of the Jackson network paradigm, simply because of the routing requirements. The OMQN model is

useful because it allows for quite general, complex routing configurations.

Multiclass queueing network models have applications in manufacturing, telecommunications, supply chain, and service systems. There has also been a significant amount of theoretical work on these models, starting mostly in the late 1980s. Although many papers contributed to the overall development of these models, the first widely accepted canonical description of these models appeared in a paper by Harrison [1]. In the 1990s, researchers initiated several significant research streams devoted to analyzing OMQNs. One major stream has been devoted to studying the stability behavior, especially via the fluid model. A second stream has investigated heavy traffic, or diffusion approximations. Finally, much work has been devoted to finding optimal or near optimal scheduling policies (see **Conservation Laws and Related Applications**). Since several other articles cover specific topics in analysis and control of OMQNs, this article is primarily restricted to introducing the modeling framework.

FORMAL MODEL DESCRIPTION

In this section, we provide the formal mathematical description of an OMQN. Our notation is consistent with the primary references in the literature, which include Refs 2–4. An OMQN consists of J single-server stations and K classes of customers, where $K \geq J$. Stations are labeled $j = 1, \dots, J$ and classes are labeled $k = 1, \dots, K$. Each class k is associated with a unique station $s(k)$. The set of classes served at station j is denoted by $C(j)$.

We first describe three primitive cumulative processes. The number of customers that arrive from outside the network to class ℓ up to time t is given by $E_\ell(t)$. For each integer $n > 0$, $V_\ell(n)$ is the total service requirement for the first n class ℓ customers. This service requirement is given in units of time. Next, for each integer $n > 0$, $\Phi_\ell^k(n)$ counts the total number of class k jobs that go to class ℓ , among the first n class k jobs that complete service at station $s(k)$. We let $\Phi^k(n)$ be the associated K -dimensional vector. These three

processes are often referred to as the *primitive cumulatives*. The primitive cumulatives embody all of the randomness in the queueing dynamics and the other performance processes of the network can be derived (in a deterministic manner) from these processes.

In most modeling contexts, it is useful to assume that the processes above have properties that are related to the strong law of large numbers. In particular, we assume that w.p. 1,

$$\lim_{t \rightarrow \infty} \frac{E_k(t)}{t} = \alpha_k, \quad (1)$$

$$\lim_{n \rightarrow \infty} \frac{V_k(n)}{n} = m_k, \quad (2)$$

$$\lim_{n \rightarrow \infty} \frac{\Phi_\ell^k(n)}{n} = P_{k,\ell}, \quad (3)$$

for $k, \ell \in \{1, \dots, K\}$. For example, if inter-arrival times of class ℓ customers are i.i.d. random variables with mean $1/\alpha_k$, then Equation (1) holds w.p. 1 by the strong law of large numbers for renewal processes. Then, one interprets α_ℓ as the long-run arrival rate for class ℓ customers. Similarly, if processing times for customers of type ℓ are i.i.d. random variables with mean m_ℓ , then Equation (2) holds w.p. 1 by the usual strong law of large numbers. Finally, if the network uses *Bernoulli routing*, then Equation (3) also holds w.p. 1 by the strong law of large numbers. However, it should be noted that the assumptions made in Equations (1–3) allow for much more general arrival, service, and routing processes.

The K -dimensional column vectors of arrival rates and mean service times are given by $\alpha = (\alpha_1, \dots, \alpha_K)'$ and $m = (m_1, \dots, m_K)'$, respectively. We also define $\mu_\ell = 1/m_\ell$ to be the service rate for class ℓ customers. The $K \times K$ matrix $P = [P_{k,\ell}]$ is called the *routing matrix* for the network. Note that we allow customers to be routed back to the same class at which they just completed service. After a customer of class k completes service, the customer is either routed to a station or leaves the network. In the case of *Bernoulli routing*, we interpret

$P_{k,\ell}$ as the probability that a class k customer becomes a class ℓ customer (at station $s(\ell)$) after service. The probability the customer leaves the network is then

$$1 - \sum_{\ell=1}^K P_{k,\ell}.$$

Recall that we assume that the network is *open*, which means that all customers leave the network w.p. 1. This is equivalent to assuming that

$$R := I + P' + (P')^2 + \dots$$

is finite, which is also equivalent to assuming that $(I - P')$ is invertible. In this case, we have $R = (I - P')^{-1}$ (Lemma 2.1, Chapter 6 in Ref. 5). Finally, in the sections below, we let $Q_k(t)$ denote the number of class k customers present in the network at time t . Such customers may either be waiting in line or in service at station $s(k)$.

Special Cases

Certain subclasses of OMQNs have been studied in the literature. We have already mentioned the case when $J = K$, in which the network is single-class network or *generalized Jackson network*. If, in addition to having $J = K$, all service and interarrival distributions are exponential, and the routing is Bernoulli, then the network is a classical Jackson network [6,7]. *Kelly networks* are also special cases of OMQNs, see the related encyclopedia article for more details.

Some other special cases rely in a more detailed way on the structure of the routing matrix P . The first definition is adapted from Chen and Yao [8], which studies networks with an acyclic transfer mechanism.

Let

$$\mathcal{I}(k) \equiv \{i = 1, \dots, K : P_{i,\ell_1} P_{\ell_1,\ell_2} \dots P_{\ell_n,k} > 0 \\ \text{for some } \ell_1, \dots, \ell_n\}$$

that is, $\mathcal{I}(k)$ is the set of classes from which class k is reachable. An OMQN is said to be an *acyclic transfer mechanism network* (ACTN) if $k \notin \mathcal{I}(k)$ for all classes $k = 1, \dots, K$. Essentially, customers in an ACTN cannot

pass through any given buffer more than once.

An OMQN is a *multitype network* (MTN) if

- $P_{\ell,k}$ is 0 or 1 for every $\ell, k \in \{1, \dots, K\}$.
- For every class k , there exists at most one class ℓ , such that $P_{\ell,k} > 0$.
- For every class k , $\alpha_k > 0$ if there are no classes ℓ , such that $P_{\ell,k} > 0$.

In other words, an MTN can be thought of a network which processes a number of products (or customer types) each of which traverses a deterministic route through the network. An MTN with only one type is called a *reentrant line*. The classes in a reentrant line can be numbered such that $P_{k,\ell} = 1$ if $\ell = k + 1$ and for which $P_{k,\ell} = 0$ otherwise. In other words, all customers follow one deterministic route through the stations. See the article for some examples of results which hold for these special cases.

SCHEDULING POLICIES

The aspect of control of OMQNs is discussed in this section. In particular, what has not yet been described is the order of service provided to customers at each station. A rule which determines this order of service at all times is called a *scheduling policy*. In other contexts, such rules may be called *service disciplines* or *dispatch policies*. Scheduling policies may be *idling* or *nonidling*. When the network is operating under a nonidling policy, each station must devote its full capacity to processing customers, whenever customers are present at the station. In most cases, it is more efficient to use a nonidling discipline, but this depends highly on the structure of the network and the performance goals. For simplicity of exposition, we restrict ourselves to nonidling disciplines here.

In general, scheduling policies may be of the processing sharing type, that is, the server at each station is allowed to simultaneous process several jobs, sharing its total capacity in some manner among the jobs. For mathematical tractability, much of the work in OMQNs is restricted to the case in which policies are *head-of-the-line* (HL).

Under an HL policies, at most one job from each class in $C(j)$ can be in process simultaneously at station j . Note that “in process” also refers to jobs that have been partially processed and are then preempted temporarily by other jobs. This restriction is important in both fluid and diffusion approximations to OMQNs. Under non-HL policies, the state descriptor for the network process is more complex, often requiring a so-called measure-valued process [9].

Two standard policies that have been studied extensively in the literature on single-station systems are FIFO (first-in-first-out) and LIFO (last-in-first-out) (see **Queueing Disciplines** for further discussion). Note that the preemptive version of LIFO is not an HL policy. Generally speaking, in the network setting neither of these policies is appealing. In fact, FIFO, has been shown to have very poor performance in OMQNs [10,11]. However, a reasonable modification of FIFO is the FISFO (first-in-system-first-out) policy. Under FISFO, customers are given a time stamp when they enter the system and carry this time stamp throughout their sojourn in the network. When a station becomes free, it chooses the customer with the earliest time stamp. One can argue that FISFO is the appropriate generalization of single station inspired FIFO policies, when working in the network setting. Furthermore, FISFO does not exhibit the undesirable properties of FIFO in this setting [12].

One class of policies that is important in the study of OMQNs is the set of *static buffer priority* (SBP) policies. Under such a policy, all the classes served at station j are given a fixed ranking. When the station becomes free, it serves the job at the HL in the highest ranking class in which customers are present. It is usually assumed that within each class, customers are lined up in FIFO order. The SBP policies are subdivided into those that preempt a low-ranking customer when a higher-ranking customer arrives, and those that allow the low-ranking customer to complete service. Furthermore, preemptive SBP policies may require preempted jobs to begin service anew, or to continue

service at the point at which it was interrupted (these are called *preemptive resume* policies). Special cases of SBP policies can be defined under certain network topologies. For example, in a reentrant line, two policies of interest are FBFS (first-buffer-first-served) and LBFS (last-buffer-first-served). Under FBFS, those classes with lower indices have higher rankings. Under LBFS, those classes with higher indices have higher rankings. Both of these policies have good properties with respect to stabilizing OMQNs [13].

Another class of policies of interest are HL processor-sharing policies, which have applications in computer systems modeling. The class of generalized head-of-the-line processor-sharing (GHLPS) policies is parameterized by a proportion vector $\beta = (\beta_1, \dots, \beta_K) > 0$. At each instant, the station shares its capacity among all the customers at HL in any nonempty class, where the proportion of capacity devoted to k customers at time t is given by

$$\frac{\beta_k \cdot 1\{Q_k(t) > 0\}}{\beta_1 \cdot 1\{Q_1(t) > 0\} + \dots + \beta_K \cdot 1\{Q_K(t) > 0\}},$$

where $1\{A\}$ is an indicator function for event A . A related class of policies are the generalized HL proportional processor-sharing policies. Again, these policies are parameterized by a positive vector $\beta = (\beta_1, \dots, \beta_K) > 0$, now called the *weight vector*. Similar to the GHLPS policies, at each instant, the station shares its capacity among customers at HL in each nonempty class. However, now the proportion dedicated to class k at time t is weighted by the number of customers in the class:

$$\frac{\beta_k \cdot Q_k(t)}{\beta_1 \cdot Q_1(t) + \dots + \beta_K \cdot Q_K(t)}.$$

TRAFFIC EQUATIONS

In OMQNs an important quantity is the *total arrival rate* λ_ℓ , for each class $\ell \in \{1, \dots, K\}$. For class ℓ , λ_ℓ is the long-run rate at which customers of class ℓ arrive at buffer ℓ as a result of internal routing and exogenous

arrivals, assuming that the network is stable (a notion to be discussed shortly). The total arrival rate is given by the *traffic equations*:

$$\lambda_\ell = \alpha_\ell + \sum_{k=1}^K \lambda_k P_{k,\ell}. \quad (4)$$

These equations can be written more compactly in vector form: $\lambda = \alpha + P'\lambda$, where $\lambda = (\lambda_1, \dots, \lambda_K)'$. The classic traffic equations for a Jackson network have the same form as those presented above in Equation (4). Since we assumed that P corresponds to an open network, these equations have a unique solution given by $\lambda = R\alpha$.

The total arrival rates can then be used to define the traffic intensity at each station $j \in \{1, \dots, J\}$:

$$\rho_j = \sum_{k \in C(j)} m_k \lambda_k.$$

One can interpret ρ_j as the average amount of work that arrives at station j per unit time, in the long run.

The traffic intensity plays a role in stability analysis of queueing networks. Roughly speaking, a network is stable if the number of customers in the system does not grow without bound over time. Various more precise notions of stability are discussed in the article. For certain definitions of stability, the *usual traffic conditions* must hold for the network to be stable:

$$\rho_j < 1, \quad \text{for all } j = 1, \dots, J.$$

In other cases, it is sufficient for a weaker form of the usual traffic conditions to hold:

$$\rho_j \leq 1, \quad \text{for all } j = 1, \dots, J.$$

QUEUEING NETWORK EQUATIONS

In order to precisely describe the evolution of multiclass queueing networks, we present the equations governing the dynamics of a network. To facilitate the mathematical description we introduce several new processes.

Let $A_\ell(t)$ denote the total numbers of class ℓ arrivals (internal and external) up to time t . $T_\ell(t)$ is the total amount of time that server $s(\ell)$ has spent serving class ℓ jobs and $D_\ell(t)$ is the total number of jobs that have completed processing up to time t . Finally, let $W_j(t)$ be the *immediate workload process* for station j . In particular, $W_j(t)$ represents the total amount of time required to finish all the work currently at the station. We let $A(t)$, $T(t)$, and $D(t)$ denote the natural K -dimensional column vectors and $W(t)$ denote the J -dimensional column vector of the workload processes. Note that one can think of $\{T(t), t \geq 0\}$ as the network control, that is, given the primitive cumulatives and the K -dimensional process $T(\cdot)$, the queueing dynamics are completely determined, as will be seen in the equations below. Furthermore, the scheduling policies discussed in the section titled “Scheduling Policies” determine the effort that is allocated to each class at each time instant, and thus a properly defined scheduling policy should uniquely determine $T(\cdot)$ for a given sample path of the primitive cumulatives.

We are now ready to present the queueing network equations:

$$A(t) = E(t) + \sum_{k=1}^K \Phi^k(D_k(t)), \quad (5)$$

$$Q(t) = Q(0) + A(t) - D(t), \quad (6)$$

$$W(t) = CV(A(t) + Q(0)) - CT(t). \quad (7)$$

Above, C is the $J \times K$ *constituency matrix* whose elements are

$$C_{j,k} = \begin{cases} 1 & \text{if } k \in C(j), \\ 0 & \text{otherwise.} \end{cases}$$

The first equation expresses the fact the total arrivals are equal to the internal arrivals plus external arrivals. Equation (6) is simply an input–output equation. The last equation precisely defines the notion of immediate workload discussed above in the following sense. The term $A(t) + Q(0)$ embodies the number of jobs that have arrived at each

station (or that were present at time 0) in the network up to time t . Applying the operator $V(\cdot)$ “converts” jobs into units of work. The constituency matrix C sums the work from the job classes according to stations. Thus, each component of $CV(A(t) + Q(0))$ gives the amount of work presented to each station up to time t . Each component in the second term in Equation (7) is the amount of time each station has worked during $[0, t]$. Therefore, the difference of the terms gives the current workload at each station.

Equations (5–7) represent the dynamics of the network under control policy $\{T(t), t \geq 0\}$. For $T(\cdot)$ to be *feasible* it must satisfy: $CT(t) \leq t$ for all $t \geq 0$. (Here, the vector inequality is interpreted componentwise). This requirement simply says no station can devote more than 100% of its time to processing customers.

If, in addition, one wishes to restrict the control to nonidling scheduling policies, then the following additional equations must be satisfied:

$$CT(t) + Y(t) = et \quad (8)$$

$$\begin{aligned} Y_j(t) \text{ can increase only when } W_j(t) &= 0, \\ j &= 1, \dots, J, \end{aligned} \quad (9)$$

where e is the column vector of all 1s and $Y_j(\cdot)$ is the cumulative idleness process at station j (note that idleness “accumulates” whenever a station works at less than full capacity). Since the $Y_j(\cdot)$ are continuous, Equation (9) can be rewritten as follows:

$$\int_0^\infty W_j(t) \, dY_j(t) = 0.$$

This representation is useful when developing approximations (such as fluid models) related to OMQNs.

Equations (5–9) constitute the nonidling queueing network equations. Yet another equation is added when the policy under consideration is HL. HL policies must also satisfy

$$V(D(t)) \leq T(t) \leq V(D(t) + e). \quad (10)$$

To understand this equation, consider a particular class k . Under any service policy (HL

or not), for each fixed t we must have $T_k(t) \geq V_k(D_k(t))$, since the right-hand side is the amount of time that was needed to process the $D_k(t)$ class k jobs, which were processed in $[0, t]$. Next, at any fixed time t , job $D_k(t) + 1$ has not yet departed station $s(k)$. Under an HL policy, only this job will receive service next, hence $T_k \leq V_k(D_k(t) + 1)$. This need not be true under a non-HL policy such as the processor-sharing discipline in which every class k job receives service simultaneously.

However, Equations (5–10) are still very general in that a large class of policies satisfy these equations. When a particular scheduling policy is considered, more equations need to be added to Equations (5–10). We consider two examples below.

FIFO Multiclass Queueing Networks

In an OMQN operating under the FIFO-scheduling policy, jobs at each station are served in the order in which they arrived at the station. This requires the imposition of additional queueing equations:

$$\begin{aligned} D_k(t + W_j(t)) &= Q_k(0) + A_k(t), \\ k &= 1, \dots, K, \end{aligned} \quad (11)$$

for all $t \geq 0$. It may not be immediately obvious that Equation (11) is equivalent to one’s intuitive notion of the FIFO policy. To gain some intuition, consider the case when $Q_k(0) = 0$, in which case, the equation is $D_k(t + W_j(t)) = A_k(t)$. Since $W_j(t)$ is exactly the amount of time required to process the class k jobs present at time t , this expression implies that the processing time during $[t, t + W_j(t)]$ was spent only on jobs that were present at time t . In particular, later-arriving jobs were not processed ahead of those job present at time t .

Thus Equations (5–11) constitute the queueing networks equations for a FIFO OMQN. However, these equations do not uniquely determine the evolution of the network without additional initial conditions, that is, it is not enough to only specify $Q(0)$. We must also give the initial order of the customers at each station. Equivalently, one

can specify the following initial part of the departure process from each class:

$$\{D_k(t) \text{ for } t \leq W_j(0), \quad k = 1, \dots, K\}.$$

Thus Equations (5–11) plus these initial conditions uniquely determine the dynamics of the network, for a given sample path of the primitive processes.

Static Buffer Priority Policies

As mentioned in the section titled “Scheduling Policies”, the set of SBP policies is an important class of policies in which the classes at the station are ranked in a fixed order. Under an SBP policy, additional network equations are again needed to specify the network dynamics. There are several variations of SBP policies. For simplicity, we focus on preemptive resume SBP. Now for any class k let $\Theta(k)$ be the set of classes with the same or higher priority than class k . Then we define the following auxiliary processes:

$$Q_k^+(t) = \sum_{\ell \in \{C(s(k)) \cap \Theta(k)\}} Q_\ell(t)$$

$$\text{and } T_k^+(t) = \sum_{\ell \in \{C(s(k)) \cap \Theta(k)\}} T_\ell(t).$$

An SBP policy with a given ranking can be characterized as follows:

$t - T_k^+(t)$ can increase only when

$$Q_k^+(t) = 0 \quad k = 1, \dots, K. \quad (12)$$

Essentially, Equation (12) indicates that for a fixed class k , the idleness process for class k jobs and higher priority jobs can increase only when no such jobs are present. Put another way, if class k or higher priority jobs are present, then 100% of processing time is devoted to those jobs. Equations (5–10) and Equation (12) constitute the SBP queueing networks equations. The initial data for an SBP policy is simply the initial queue length vector $Q(0)$.

FURTHER TOPICS

Additional details on the framework discussed in this article can be found in Refs 2–4. We have not discussed the case where the network is *closed*. In such a network, a finite number of jobs circulate forever in the network [14–17]. Obviously, other enhancements to the basic framework are possible. For example, some researchers have considered OMQNs with setups, batching, or parallel servers [18,19]. Another important extension is to so-called flexible server networks, which are discussed in the article. A further generalization is described. Several other articles discuss analysis and control of OMQNs, including ***Conservation Laws and Related Applications***, and ***Performance Bounds in Queueing Networks***.

INTRODUCTION

In many applications, several physical commodities share the same network, yet each is governed by its own network flow constraints. For example, in telecommunications applications, telephone calls between specific node pairs in an underlying telephone network each define a separate commodity. However, all these commodities share common telephone line resources. In this article, we study the *multicommodity network flow problem*, which can be used to model such problems. Let $G(N, A)$ denote the underlying network with node set N and arc set A . Each arc has a capacity u_{ij} that restricts the total flow of all commodities on it. The objective of the problem is to send several commodities that reside at one or more points in a network (sources or supplies) to one or more points on the network (sinks or demands), incurring minimum cost. The arc capacities bind the flows of all commodities together and complicate the problem. If the common arc capacity constraints are relaxed, the multicommodity flow problem can be solved as several independent minimum cost flow problems.

Let K be the set of all commodities, decision variable x_{ij}^k be the flow of commodity $k \in K$ on arc (i, j) , x^k be the flow vector of commodity $k \in K$, c^k be the cost vector for commodity $k \in K$, b^k be the supply/demand vector for commodity $k \in K$, u_{ij}^k be the maximum flow of commodity $k \in K$ on arc $(i, j) \in A$, and u_{ij} be the total capacity of arc $(i, j) \in A$.

Then, the multicommodity flow problem is formulated as follows:

$$\begin{aligned} & \text{Minimize } \sum_{k \in K} c^k x^k \\ & \sum_{k \in K} x_{ij}^k \leq u_{ij}, \text{ for all } (i, j) \in A \\ & \sum_{\{j: (i, j) \in A\}} x_{ij}^k - \sum_{\{j: (j, i) \in A\}} x_{ji}^k = b_i^k, \text{ for all } i \in N, k \in K \\ & 0 \leq x_{ij}^k \leq u_{ij}^k, \text{ for all } (i, j) \in A, k \in K. \end{aligned}$$

The first set of constraints (*bundle constraints*) link the different commodities by restricting the total flow on each arc by its capacity. The second set of constraints ensures the flow balance of each commodity at each node in the network, and the third set of constraints imposes individual bounds on the flow of each commodity on each arc. The integrality of solutions is one very important distinguishing feature between single and multicommodity flow problems. One particularly beneficial feature of single-commodity network flow problems (or minimum cost flow problems) is that they always have integer solutions when the supply/demand and capacity data are integer-valued. For multicommodity flow problems, however, this is not the case [1].

The three basic approaches for solving multicommodity flow problems are (i) price-directive decomposition algorithm [2–8]; (ii) resource-directive decomposition algorithm [5, 9, 10]; and (iii) basis partitioning [11–13]. Ford and Fulkerson [14] and Tomlin [15] first suggested the column generation approach. The first of these papers was the forerunner to the general [16] decomposition procedure of mathematical programming. The excellent survey papers by Assad [17] and Kennington [18] describe all these algorithms and several standard properties of multicommodity flow problems. The book by Kennington and Helgason [12] and the doctoral dissertation by Schneur [19] are other valuable references on this

topic. Other algorithms for the multicommodity flow problem are due to Barnhart [20], Barnhart and Sheffi [21], Farvolden *et al.* [22], Frangioni and Gallo [23], and Detlefsen and Wallace [24]. Schneur [19] and Schneur and Orlin [25] studied scaling techniques for the multicommodity flow problem. Barnhart *et al.* [26] developed a column generation model and an integer programming based branch-and-price-and-cut algorithm for integral multicommodity flow problems. Brunetta *et al.* [27] investigated polyhedral approaches and branch-and-cut algorithms for the integral version.

Multicommodity network flow models have been widely applied in several domains. Some interesting applications are due to the following [5, 28–40].

The general integral version of the multicommodity problem is NP-complete. In this article, we consider the multicommodity flow problem under the assumption that the flow variables can be fractional. This problem is a linear programming problem, and therefore polynomially solvable. While this is a simplifying assumption, techniques to solve the nonintegral version give us a basic understanding and often serve as building blocks for algorithms for the integral version. For example, the branch-and-price-and-cut algorithm for integral multicommodity flow problems is based on the column generation algorithm for the nonintegral version. The rest of this article is organized as follows. In the section titled “Applications,” we identify some applications of the multicommodity flow problem; in the section titled “Optimality Conditions,” we discuss the optimality conditions; and finally in the section titled “Multicommodity Flow Algorithms,” we describe algorithms to solve the problem.

APPLICATIONS

Multicommodity flow problems arise in a wide variety of application contexts where (i) several physically distinct commodities flow over a common network and (ii) a single commodity flows over the network, but it has multiple points of origin and destination that need to send the commodities to each other. We now introduce both kinds of applications.

Figure 1. Multicommodity flow problem.

Communication Networks. Nodes represent the origin and destination points for messages, and arcs represent the transmission lines. The messages between different pairs of nodes represent the different commodities, and the supply and demand for each commodity is the number of messages that must be sent between its origin and destination. Each transmission line has a fixed capacity that is shared by all the messages that are routed through it. The problem of determining the minimum cost routing of messages is a multicommodity flow problem. Figure 1 gives an illustration of a problem with two commodities: commodity 1 containing f_1 messages that must be sent from node 8 to node 1, and commodity 2 containing f_2 messages that must be sent from node 7 to node 2.

Railroad Networks. In the railroad context, yards and junction points represent the nodes, and the tracks represent arcs in the network. Since the system incurs various costs for different goods, we divide traffic demand into separate classes. Each commodity in this network corresponds to a particular class of demand between a particular origin–destination pair. The bundle capacity of each arc is the number of railcars that we can load on the trains scheduled to be

dispatched on that arc (over some period of time). The decision problem is to meet the demand of cars at the minimum possible operating cost.

Distribution Networks. In distribution systems planning, we wish to distribute multiple products from plants to retailers using a fleet of trucks or railcars with a variety of railheads and warehouses. The products define the commodities of the multicommodity flow problem, and the joint capacities of the plants, warehouses, rail yards, and the shipping lanes define the bundle constraints. These applications may have bundle constraints imposed on the nodes (warehouses/plants) as well as arcs; such bundle constraints can be handled by the multicommodity flow framework using a node-splitting transformation.

OPTIMALITY CONDITIONS

Since the multicommodity flow problem is a linear program, we can use linear programming optimality conditions to characterize optimal solutions to the problem. The dual has two types of variables: a *price* w_{ij} corresponding to each arc's bundle constraint, and a node potential $\pi^k(i)$ corresponding to commodity k 's flow balance constraint at node i (we assume that the flow variables x_{ij}^k are unbounded). Using the dual variables, we define reduced cost $c_{ij}^k(\pi)$ of arc (i, j) with respect to commodity k as $c_{ij}^k(\pi) = c_{ij}^k - \pi^k(i) + \pi^k(j) + w_{ij}$.

Next, we write the dual of the multicommodity flow problem

$$\begin{aligned} & \text{Maximize } - \sum_{(i,j) \in A} u_{ij} w_{ij} + \sum_{k \in K} b^k \pi^k \\ & c_{ij}^k(\pi) = c_{ij}^k - \pi^k(i) + \pi^k(j) + w_{ij} \geq 0, \\ & \quad \text{for all } (i, j) \in A, k \in K \\ & w_{ij} \geq 0, \text{ for all } (i, j) \in A. \end{aligned}$$

The optimality conditions for linear programming are called the *complementary slackness (optimality) conditions* and state that a primal feasible solution x and a dual

feasible solution are optimal to the respective problems, if and only if the product of each primal variable and the slack in the corresponding dual constraint is zero. The complementary slackness conditions for the primal-dual pair of the multicommodity flow problem are as follows.

Multicommodity Flow Complementary Slackness Conditions. *The commodity flows x_{ij}^k are optimal for the multicommodity flow problem with each $u_{ij}^k = +\infty$ if and only if they are feasible and for some choice of arc prices $w_{ij} \geq 0$ and node potentials $\pi^k(i)$, the reduced costs and arc flows satisfy the following complementary slackness conditions:*

- (a) $w_{ij} \left(\sum_{k \in K} x_{ij}^k - u_{ij} \right) = 0$ for all $(i, j) \in A$;
- (b) $c_{ij}^k(\pi) = c_{ij}^k - \pi^k(i) + \pi^k(j) + w_{ij} \geq 0$, for all $(i, j) \in A, k \in K$;
- (c) $c_{ij}^k(\pi) x_{ij}^k = 0$ for all $(i, j) \in A, k \in K$.

In the next section, we describe algorithms that use the complementary slackness conditions to solve the multicommodity flow problem.

MULTICOMMODITY FLOW ALGORITHMS

In this section, we describe two techniques to solve the multicommodity flow problem, namely, Lagrangian relaxation and Dantzig-Wolfe Decomposition.

Lagrangian Relaxation

Lagrangian relaxation is a general solution strategy for solving mathematical programs that permit us to decompose problems to exploit their special structure. It works by moving hard constraints to the objective function and penalizing their violation. For the multicommodity flow problem, the complicating constraints are the bundle constraints. We move these constraints to the objective function by associating nonnegative Lagrangian multipliers w_{ij} with the bundle constraints and creating the

following Lagrangian subproblem.

$$\begin{aligned}
L(w) = & \text{minimize } \sum_{k \in K} \sum_{(i,j) \in A} c_{ij}^k x_{ij}^k \\
& + \sum_{(i,j) \in A} w_{ij} \left(\sum_{k \in K} x_{ij}^k - u_{ij} \right) \\
= & \sum_{k \in K} \sum_{(i,j) \in A} (c_{ij}^k + w_{ij}) x_{ij}^k - \sum_{(i,j) \in A} w_{ij} u_{ij} \\
& \sum_{\{j:(i,j) \in A\}} x_{ij}^k - \sum_{\{j:(j,i) \in A\}} x_{ji}^k = b_i^k, \text{ for all } i \in N, k \in K \\
& x_{ij}^k \geq 0, \text{ for all } (i,j) \in A, k \in K.
\end{aligned}$$

The second term in the objective function is a constant for a given set of Lagrangian multipliers and can be ignored. Also, since the bundling constraints that link the different commodity flows are relaxed, the Lagrangian subproblem can be solved efficiently as k independent, minimum-cost flow problems. For any value of Lagrangian multipliers, it can be shown that $L(w)$ is a lower bound to the optimal objective function of the original problem. The tightest possible lower bound is obtained by solving the Lagrangian multiplier problem $L^* = \max_w L(w)$. The Lagrangian multipliers w for which $L(w) = L^*$ are called the *optimal Lagrangian multipliers*. The following theorem, stated without proof, is the basis for Lagrangian relaxation used to solve the multicommodity flow problem.

Theorem 1. *Suppose we apply the Lagrangian Relaxation technique to a linear programming problem, the optimal value L^* of the Lagrangian multiplier problem equals the optimal objective function value of the linear programming problem.*

Lagrangian relaxation is a price-directive decomposition method to solve the multicommodity flow problem. From Theorem 1, it follows that by solving the Lagrangian multiplier problem, we obtain the optimal solution of the multicommodity flow problem. Subgradient optimization is a commonly used technique to solve the Lagrangian multiplier problem. This method iteratively does the following: (i) given a set of Lagrangian multipliers (w), it solves the multicommodity flow

problem as $|K|$ independent minimum cost flow problems with cost coefficients $c_{ij}^k + w_{ij}$; and (ii) updates the multipliers based on the solution obtained in (i). It can be shown that, by choosing a suitable step size to update the multipliers, the subgradient method terminates in a finite number of steps to the optimal multipliers. Lagrangian relaxation is a popular method to solve the multicommodity flow problem owing to its ease of implementation and empirical performance.

Dantzig-Wolfe Decomposition

To simplify our discussion, we consider a special case of the multicommodity flow problem: we assume that each commodity k has a single source node s^k and a single sink node t^k , and a flow requirement of d^k units between these source and sink nodes. We also assume that there are no flow bounds on the individual commodities other than the bundle constraints. Therefore, for each commodity k , the subproblem constraints $\sum_{\{j:(i,j) \in A\}} x_{ij}^k - \sum_{\{j:(j,i) \in A\}} x_{ji}^k = b_i^k, x_{ij}^k \geq 0$ define a shortest path problem. We also assume that the cost of every cycle in the network is nonnegative for each commodity. Hence, any potential optimal solution can be represented as the sum of flows on directed paths.

Path Flow Reformulation. For each commodity k , let P_k denote the set of all directed paths from the source node s^k to the sink node t^k in the underlying network. In the path flow formulation, we consider one decision variable $f(P)$ for the flow on each path $P \in P_k$ for commodity k . Let $d_{ij}(P)$ be 1 if arc (i,j) is contained in path P , and 0 otherwise. Then, the flow decomposition theorem of network flows states that we can always decompose the optimal arc flow x_{ij}^k into path flows $f(P)$ such that $x_{ij}^k = \sum_{P \in P_k} f(P) d_{ij}(P)$. Hence, the multicommodity flow problem can be reformulated as follows:

$$\begin{aligned}
& \text{Minimize } \sum_{k \in K} \sum_{P \in P_k} c^k(P) f(P) \\
& \sum_{k \in K} \sum_{P \in P_k} d_{ij}(P) f(P) \leq u_{ij}, \text{ for all } (i,j) \in A
\end{aligned}$$

$$\sum_{P \in P_k} f(P) = d^k, \text{ for all } k \in K$$

$$f(P) \geq 0, \text{ for all } P \in P_k, k \in K.$$

The path flow formulation has a simple structure. It has one constraint that bounds the flow on each arc in the network, and it has one constraint for each commodity that ensures the demand for that commodity is satisfied. The path-based formulation implicitly takes care of the flow balance constraints for each commodity at every node in the network. For a network with n nodes, m arcs, and K commodities, this formulation contains $m + K$ constraints in addition to the nonnegativity constraints on path flows.

Optimality Conditions. Since the path flow formulation contains one bundle constraint for each arc and one demand constraint for every commodity, the dual linear program has a dual variable w_{ij} for each arc and another dual variable r^k for each commodity $k \in K$. With respect to these dual variables, the reduced cost for each path flow variable $f(P)$ is $C_P(w, r) = c^k(P) + \sum_{(i,j) \in P} w_{ij} - r^k$. The complementary slackness optimality conditions for the linear programming problem take the following form.

Path Flow Complementary Slackness Optimality Conditions. The commodity path flows $f(P)$ are optimal if and only if we can find (non-negative) arc prices w_{ij} and commodity price r^k so that the reduced costs and arc flows satisfy the following complementary slackness conditions:

- (a) $w_{ij}(\sum_{k \in K} \sum_{P \in P_k} d_{ij}(P)f(P) - u_{ij}) = 0$, for all $(i, j) \in A$;
- (b) $C_P(w, r) \geq 0$ for all $P \in P_k, k \in K$;
- (c) $C_P(w, r)f(P) = 0$ for all $P \in P_k, k \in K$.

The Dantzig–Wolfe decomposition method works in the following manner. Imagine that K different decision makers, as well as one “coordinator,” are solving the K -commodity flow problem. The coordinator’s job is to solve the path formulation of the problem, which we refer to as the “master” or “coordinating”

problem. In general, the coordinator has on hand only a subset of the columns of the master problem. Since the coordinator can, at best, solve the linear program as restricted to this subset of columns, we refer to this smaller linear program as *the restricted master problem*. Each of these K decision makers plays a special role in solving the problem. The K decision makers, with guidance from the coordinator in the form of arc prices, generate entering variables or columns, with the k th decision maker generating the columns of the master problem corresponding to the k th commodity.

The coordinator solves the restricted master problem to optimality using any linear programming technique, such as the simplex algorithm, and then determines whether the solution to the restricted master is optimal for the original problem, or if another column has a negative reduced cost and can enter the basis. The coordinator broadcasts the optimal set of simplex multipliers (or prices) for the restricted master problem: w_{ij} corresponding to each arc $(i, j) \in A$ and r^k corresponding to each commodity $k \in K$.

Once the coordinator has broadcast the prices, the decision maker for commodity k determines the least cost way of shipping d^k units from the source node s^k to the sink node t^k of commodity k , assuming that each arc (i, j) has an associated toll of w_{ij} in addition to its arc cost c_{ij}^k . If the cost of the shortest path is less than r^k , it implies that the corresponding reduced cost $C_P(w, r)$ is negative. The k th decision maker will report this path to the coordinator as an improving path, and the decision variable corresponding to this path becomes a candidate to enter the basis. If the cost of this path equals r^k , then the k th decision maker will not report anything to the coordinator. The cost of the path can never be more than r^k because the current solution is optimal to the restricted master problem, and the coordinator is already using some path of cost r^k for the k th commodity in the current solution. The algorithm terminates when no decision maker finds a candidate path to enter the basis (complementary slackness conditions are satisfied).

To dynamically generate entering variables or columns, we solve a shortest path problem; hence, the Dantzig–Wolfe decomposition method is an example of the column generation method for solving linear programming problems. Also, notice that the K subproblems correspond to the Lagrangian relaxation problem with an additional multiplier cost of w_{ij} imposed upon each arc (i, j) . Consequently, we could view the coordinator as setting the Lagrangian multipliers and solving the Lagrangian multiplier problem. In fact, Dantzig–Wolfe decomposition is an efficient method for solving the Lagrangian multiplier problem if we measure efficiency by the number of iterations an algorithm performs.

Unfortunately, in applying Dantzig–Wolfe decomposition, the coordinator must solve a linear program with $m + K$ constraints at each iteration. This method for updating simplex multipliers is far more time consuming than updating the multipliers using subgradient optimization. Hence, the Dantzig–Wolfe decomposition method has generally not proven to be an efficient method for solving the multicommodity flow problem. Nevertheless, Dantzig–Wolfe decomposition has one important advantage that distinguishes it from other Lagrangian relaxation-based algorithms. It can be shown that the solution to the subproblems provides us with a lower bound on the optimal value of the problem. Consequently, at each step we also have a bound on how far the current feasible solution is from optimal. Therefore, we can terminate the algorithm at any step not only with a feasible solution but also with a guarantee of how far that solution is from optimality.

MULTIECHELON MULTIPRODUCT INVENTORY MANAGEMENT

RODNEY P. PARKER
The University of Chicago, Chicago,
Illinois

INTRODUCTION

The management of inventory when facing uncertain demand is a fundamental operational challenge and has amongst the largest pools of research in operations research. Specifically, the analysis of multiechelon systems, where there is a physical flow of goods from one installation to another, ultimately satisfying uncertain market demand, has been an active research area from the 1960s until the present day. The typical trade-off is to reduce the costs associated with holding inventory, while being responsive in providing goods to end customers in the face of uncertain demand. In this article, we initially summarize the optimal inventory policies for single installations and then discuss various multiechelon inventory systems.

SINGLE INSTALLATION INVENTORY MODELS

Appreciating the fundamentals of single installation models will facilitate the understanding of multiechelon inventory systems considered in the next section. Most inventory research utilizes discrete-time models (known as *periodic review* models), while the remainder considers a continuous-time basis (known as *continuous review* models), with the exception being the newsvendor model which considers inventory management in a single period (see ***Newsvendor Models***). We discuss about both in this section but focus on discrete-time models in subsequent sections.

Discrete-Time Single Installation

Considered the most fundamental inventory model, we examine a single installation where the objective is the optimal management of a single durable product in the face of unknown demand over multiple (discrete) time periods. Some common assumptions dealing with such models include (i) the demand probability distribution is known, (ii) the cost associated with holding physical inventory is a convex function in the inventory amount, (iii) the cost associated with unmet demand is a convex function in the demand shortfall, (iv) a specific treatment of customers whose demand is unmet. Common treatments under assumption (v) include customers' unmet demand is backlogged (where the amount of unsatisfied demand is carried into the following time period and satisfied then or thereafter), lost (where the unsatisfied demand in the current period disappears entirely), or partially backlogged and partially lost (where some proportion of the unsatisfied demand will be backlogged while the remainder will be lost).

Let us introduce some notation. Let $z^+ = \max(z, 0)$. Let x_t be the amount of inventory at the beginning of period t , a_t be the amount ordered in period t , D_t be the (unknown) demand in period t , $H(x)$ and $P(x)$ be the cost of holding or not satisfying demand for finishing inventory x , $f(x) = x^+ - \gamma(-x)^+$ be the amount of inventory/backlog in the following period if the current period ends with x and $\gamma \in [0, 1]$ is the proportion of x that will be backlogged (under this regime, a negative beginning inventory position represents that amount of backlog), and $\alpha \in [0, 1]$ be the single-period discount factor. A common assumption is to apply unit holding (h) and stockout (p) costs: $H(x) = hx^+$ and $P(x) = p(-x)^+$. We will use these unit holding and stockout costs. Let the objective be to minimize the discounted expected costs (over $T < \infty$ periods):

$$V_t(x_t) = \min_{a_t, a_{t+1}, \dots, a_T \geq 0} \mathbb{E} \left[\sum_{i=t}^T \alpha^{i-t} \times (h(x_i + a_i - D_i)^+ + p(D_i - x_i - a_i)^+) \right] \quad (1)$$

$$= \min_{a_t \geq 0} \mathbb{E} [h(x_t + a_t - D_t)^+ + p(D_t - x_t - a_t)^+ + \alpha V_{t+1}(f(x_t + a_t - D_t))] \quad (2)$$

$$V_{T+1}(\cdot) = 0, \quad (3)$$

where Equation (2) is the recursive Bellman representation of the model (see the sections titled “Dynamic Programming” and “Markov Decision Processes (MDPs)” in this encyclopedia). A common variable translation is to define $y_t := x_t + a_t$ as the new decision variable, representing the amount of inventory after the order has arrived but before demand is subtracted.

$$V_t(x_t) = \min_{y_t \geq x_t} \mathbb{E} [h(y_t - D_t)^+ + p(D_t - y_t)^+ + \alpha V_{t+1}(f(y_t - D_t))] \quad (4)$$

It is straightforward to show the operand of Equation (4) is convex in y_t in time period t . Let z_t be a quantity that minimizes the operand of Equation (4) in period t . Thus, the most desirable action in period t is to order an amount such that $y_t = z_t$. This will be possible if period t 's beginning inventory position (x_t) is lower than z_t , resulting in an ordered quantity $a_t = z_t - x_t$ (equivalently, $y_t = z_t$). However, if the beginning inventory is greater than z_t , the optimal decision is to order nothing, $a_t = 0$ or $y_t = x_t$. Thus, y_t is known as the *order up-to* quantity. Since the minimizer, z_t , is independent of the initial inventory x_t , the optimal target is known as the *base-stock* level. These statements are true in any (general) period t and constitutes the optimal inventory policy known as the *base-stock* inventory policy. The implementation of this policy requires a comparison of the inventory position at the beginning of the period (x_t) and the target stocking level (z_t), resulting in a different amount (a_t) being ordered in each period.

Now, consider an additional complication where the firm incurs a fixed cost, K , whenever an order is placed ($a_t > 0$). It should be clear that the operand is no longer convex. However, Scarf [1] showed that it is K -convex, basically a concept where a function is convex within a margin of K (a single-variable function g is K -convex if $g(x) + \lambda(g(x) - g(x - v))/v \leq g(x + \lambda) + K$ for all x and positive λ, v). Intuition should suggest that incurring an additional fixed ordering cost (independent of the quantity ordered) should lessen the frequency of ordering. The optimal policy again is a base-stock policy (with an optimal base-stock level, S_t) but an order is placed *only* when the beginning inventory level (x_t) is below $s_t (< S_t)$, a quantity known as the *trigger level*. This is known as an (s, S) policy and is optimal for systems with full backlogging or full lost sales (Heyman and Sobel [2], Chapter 7). In short, the manager will place an order (and incur the fixed cost K) only when there is a sufficient ordering quantity to warrant it. When an order is placed (when $x_t < s_t$), $S_t - x_t$ is ordered and always at least $S_t - s_t$ is ordered.

A notable omission heretofore has been the inclusion of delivery lead times. When $\gamma = 1$ (i.e., full backlogging), lead times that are a known integer multiple of the period can be included while preserving the structure of the above optimal inventory policies, as the materials in transit to the installation may be incorporated into the decision variable, simplifying the analysis. The effect of a larger lead time is for the installation to stock up to a higher level. For values of $\gamma < 1$, this optimal policy structure is destroyed and the analysis is vastly more complicated as the individual quantities in transit to the installation must be tracked within the state space. Indeed, Zipkin [3] indicates that a simple base-stock policy performs poorly compared to numerous suboptimal heuristics under a lost sales assumption ($\gamma = 0$). Kaplan [4] incorporates stochastic lead times under an assumption that orders placed with the supplier will not “cross,” that is, an order placed in period t will not arrive after an order placed in period $t' > t$. Under this condition, Kaplan [4] finds a base-stock inventory policy is optimal.

Another extension is the application of production capacity constraints in the periodic review model (this applies only when $K = 0$). Federgruen and Zipkin [5,6] show that when there is a capacity limit C on the order quantity in each period, the optimal policy is *modified base-stock*, where it is optimal to order up to a target z_t in period t , *if possible*. The last caveat applies when the beginning inventory quantity $x_t < z_t - C$. Under such circumstances $a_t = C$, the most of which can be processed in a period, thus reaching the closest feasible inventory position to z_t . Nonstationary parameters are permitted in the model with a base-stock policy remaining optimal. Also, Markov-modulated demand may also be incorporated, thus permitting demands with a degree of autocorrelation, also resulting in optimal base-stock policies.

Continuous-Time Single Installation

A commonly used policy when the manager continually assesses the inventory levels (rather than examining the inventory periodically) is to place an order of a fixed quantity (Q), whenever the inventory level falls below an ordering trigger level (r). A reasonable (and optimal for the deterministic system) approximation for the order quantity is the Economic Order Quantity (EOQ), $Q = \sqrt{\frac{2\bar{D}K}{h}}$, where $\bar{D}$ is the mean annual demand and h is the annualized unit holding cost. Define the random variable D_{LT} as the demand during the lead time. The ordering trigger level is $r = \mu + z\sigma$, where $\mu = E[D_{LT}]$, σ is the standard deviation of D_{LT} , and z is the distance from the mean of D_{LT} to the trigger level, expressed in standard deviations. z is typically set by considering the equation, $\Pr(D_{LT} > r) = \delta$, where δ is the proportion of periods in which we expect customers to experience a stockout (this is typically called a *type 1 service level*). The quantity δ is typically quite small in most retail scenarios: $\delta = 0.05, 0.01, 0.005$. The quantity $z\sigma$ is known as the *safety stock* and is the additional stock embedded in the system to compensate for the demand uncertainty. It is straightforward to see that if there is no uncertainty, there are no safety stocks and

then $r = \mu$. The above method is straightforward to calculate (and widely taught) but not optimal. To find the optimal (Q, r) parameters, it requires the recursive solution of two equations: $Q = \sqrt{\frac{2\bar{D}(K+pE(D_{LT}-r)^+)}{h}}$ and $\Pr(D_{LT} \geq r) = \frac{Qh}{p\bar{D}}$, where p is the unit shortage cost. Hadley and Whitin [7] indicate that the differences between the backlogging and lost sales cases for the values of Q and r will be small in practice.

In practical terms, the periodic review model requires fewer “inspection” costs to assess the level of inventories compared with the continuous review. As the name suggests, the periodic review measurement of inventory could be done on a daily, weekly, or monthly basis, for example, whereas inventory level must be constantly assessed under continuous review. While the latter may sound arduous, this is typically achieved using automated systems, especially for continuous quantities such as liquids (e.g., oil, sugar) or simply using the checkout scanner to deduct quantities from a virtual inventory counter, vastly reducing the assessment costs, although such scanning may be a source of potentially large error rates in the virtual inventory (see the section titled “Retail Applications” in this encyclopedia; DeHoratius and Raman [8]). Perhaps a more important consideration under this continuous-review optimal policy is that a constant quantity (Q) is ordered whenever an order is placed, which perhaps provides a practical simplicity when considering pallet sizes, truck capacities, and other considerations. In practice, the continuous review policy suggests that an order be placed at the precise time when the inventory level falls below r , which may not necessarily be convenient, given practical organizational routines. The periodic review optimal policy, however, recommends a (potentially) different amount whenever an order is placed, but the orders are placed precisely at the time when the inventory is reviewed; this will be in every period when $K = 0$ for the simple base-stock policy but may not be in every period when $K > 0$ under the (s, S) policy. Such periodic review

policies frequently dovetail with organizational norms such as “place an order every Monday.”

MULTIECHELON INVENTORY SYSTEMS

A common convention we adopt hereafter is to refer to “upstream” and “downstream” (analogizing the flow of water in a river) as directions within the channel, with the former referring to the source of the material and the latter referring to the destination (the market) of the material.

Serial Systems

The simplest multiechelon system is a serial system consisting of N installations, where each installation has (at most) a single upstream and a single downstream installation. Let installation 1 be the one closest to the market and installation N be the one most upstream closest to the “outside supplier.” The market demand is uncertain although the probability distribution is assumed known, as before. The system incurs a stockout cost for not satisfying demand. Unsatisfied demand arises when the realized demand exceeds the available inventory at installation 1 and will be carried into the following period as a backlog. Holding costs are assessed for physical inventory remaining at each installation at the end of each period. With the objective of minimizing the system-wide expected discounted costs, each installation obtains an order from its immediate upstream supplying installation; the amount delivered to installation $j < N$ in period t , a_t^j , cannot exceed installation $j + 1$ ’s inventory at the beginning of period t , x_t^{j+1} . It is assumed that installation N has no availability constraints from the “outside supplier.” Clearly, the flow of material is from upstream to downstream (installation j to installation $j + 1$) and the flow of orders is from downstream to upstream. Assume unit holding and stockout costs, where h_i is the cost of holding a unit of stock at installation i for one period and p is the unit stockout cost. We assume that $h_1 > h_2 > \dots > h_N$. We denote vectors as $\tilde{x} = (x^1, x^2, \dots, x^N)$. The

expected discounted cost is

$$V_t(\tilde{x}_t) = \min_{\tilde{a}_t} \mathbb{E} \left[h_1(x_t^1 + a_t^1 - D_t)^+ + \sum_{j=2}^N h_j(x_t^j + a_t^j - a_t^{j-1}) + p(D_t - x_t^1 - a_t^1)^+ + \alpha V_{t+1}(\tilde{x}_t + \tilde{a}_t - \tilde{D}_t) \right]$$

$$\text{s.t. } a_t^1, a_t^2, \dots, a_t^N \geq 0 \quad (5)$$

$$a_t^j \leq x_t^{j+1}, j < N \quad (6)$$

where constraints (6) state that any order quantity at an installation cannot exceed the inventory available at the immediate upstream installation at the beginning of the period. It should be noted that $x_t^j \geq 0$ for $j > 1$ but x_t^1 could be positive (reflecting physical inventory) or negative (reflecting a backlog). This formulation assumes the delivery lead time between installations is a single time period (for notational convenience), but the results of this section extend to situations where there are lead times, which are an integer multiple of the period. Clark and Scarf [9] are responsible for the analysis of this model and demonstrated the optimal inventory policy (Federgruen and Zipkin [10] showed the finite horizon model’s optimal policy extends to the infinite time horizon). This involved counting inventory in a slightly different way. The proposed counting concept known as *echelon* inventory where echelon i ’s inventory is $X_t^i := \sum_{j=1}^i x_t^j$. In short, echelon inventory is counting all the inventory at an installation and anywhere downstream of this installation which provides a natural ordering of the echelon inventories, $X_t^i \leq X_t^{i+1}$ for $i < N$. As before, backlogging of unmet demand is assumed and an installation 1 backlog is recorded as negative inventory, that is, $X_t^1 = x_t^1 < 0$. Echelon i inventory level, X_t^i , will be negative if the sum of all the downstream physical inventory, $\sum_{j=2}^i x_t^j > 0$, is less than the installation 1 backlog, $x_t^1 < 0$. There is no loss of information in the mapping from installation inventory variables to echelon inventory variables. Similar to the single installation inventory problem, the decision variables

can be modified to the order up-to levels but in echelon inventory variables: $Y_t^i = X_t^i + a_t^i = \sum_{j=1}^i x_t^j + a_t^i$. The value function becomes

$$V_t(\tilde{X}_t) = \min_{\tilde{Y}_t} \mathbb{E} \left[h_1(Y_t^1 - D_t)^+ + \sum_{j=2}^N h_j(Y_t^j - Y_t^{j-1}) + p(D_t - Y_t^1)^+ + \alpha V_{t+1}(\tilde{Y}_t - \tilde{D}_t) \right] \quad (7)$$

$$\text{s.t. } Y_t^j \geq X_t^j, j \leq N \quad (8)$$

$$Y_t^j \leq X_t^{j+1}, j < N. \quad (9)$$

Clark and Scarf [9] demonstrated that this model's objective function is convex in echelon up-to decision variables, thus establishing that an *echelon base-stock* inventory policy is optimal. The importance of this cannot be understated since there is a relationship of differently shaped supply chains to the serial system, as described in the following sections. The interpretation of this policy is that the system manager observes the echelon inventory levels at the beginning of a period (captured in the state space) and for those echelon inventory levels below the optimal echelon base-stock levels, order that difference if such a quantity is available at the immediate upstream installation; if insufficient inventory resides at the upstream installation, order as much as possible. Constraints (8) state that the echelon up to amount must exceed the initial echelon inventory while constraints (9) state the amount ordered cannot exceed the inventory available at the immediate upstream installation. Clark and Scarf [9] show the operand of Equation (7) is *convex* and *separable* in each echelon inventory variable. Since there is a natural ordering of the decision variables arising from their definition, the target minimizing echelon inventory levels, Z^i , are likewise ordered. This could be thought of a *nested* ordering of inventory where echelon i ordering up to optimal Z^i has a total of Z^i units of inventory

within $i - 1$ periods of the market (similarly, if we insert delivery lead times of L^i between the installations $i + 1$ and i , then echelon i has Z^i units within $\sum_{j=1}^{i-1} L^j$ periods of the market). Thus, this *nested* arrangement (i.e., $Z^1 \leq Z^2 \leq \dots \leq Z^N$) adds a layer of protection where, for example, if there is a large demand realization, which dramatically reduces the installation 1 inventory, all the upstream installations observe this (since they are measuring inventory in echelon terms) and immediately order quantities to compensate for this rather than wait for rippling orders to flow up the channel. Additionally, the system has a natural tension of wishing to have as much inventory close to the market as possible for sale while wishing to store the inventory further upstream to incur lower holding costs. Thus, the optimal $\tilde{Z}$ balances the echelon holding costs and the stockout cost for unmet demand at installation 1.

Solving a dynamic program with an N -dimensional state space, even one with a convex value function, can be challenging; Bellman [11] coined the phrase “curse of dimensionality” to describe this situation. Usefully, Clark and Scarf [9] additionally proved the *separability* of the system's value function, meaning it may be decomposed into N single-dimension convex dynamic programs with the echelon inventory level as the state space, vastly reducing the computational effort needed to determine the optimal echelon base-stock levels. This reduces the search for optimal echelon stocking levels to a line search for each individual dynamic program, each of which is convex and independent of the other echelons. In doing this, Clark and Scarf [9] were able to discern an insight that upon this decomposition, each installation absorbs an *induced penalty cost function*, which is a convex cost function applied when the echelon has insufficient inventory to enable the downstream echelon to reach its desired stocking level. In short, the lack of inventory at an installation increases the channel costs and this decomposed single-variable value function compensates by incurring the induced penalty cost.

Linear costs associated with “purchasing” goods by one installation from another may

be included and the echelon base-stock policy remains optimal. A fixed cost (independent of the purchased quantity) may be incurred by installation N when buying from the outside supplier. Installation N will now optimally follow an (s, S) policy (*à la* Scarf [1]), while all the other echelons follow the echelon base-stock policy as previously described. Inserting fixed ordering costs for any echelon $j < N$ creates problems and destroys the optimal policy structure described above and only approximate techniques exist, although Chen and Zheng [12] establish well-performing bounds on such problems. Shang and Song [13] derive upper and lower bounds on the optimal base-stock levels and Gallego and Zipkin [14] derive multiple heuristic methods for this system, usefully connecting the discrete-time and continuous-time versions of this model. Chen and Zheng [15] establish lower bounds on the minimum costs for serial, assembly, and single-warehouse distribution systems. Muharremoglu and Tsitsiklis [16] describe effective algorithms for solving the optimal problem using the single-unit decomposition approach.

Cachon and Zipkin [17] consider a decentralized version of the serial system operated under echelon and installation equilibrium policies, finding system-wide costs increase while equilibrium stocking levels decrease, relative to the integrated channel considered above (see the section titled “Game Theory” in this encyclopedia). The optimal inventory policy of the general N -stage serial system subject to production capacity constraints is unknown, although Parker and Kapuscinski [18] find the optimal *modified echelon base-stock* policy for the $N = 2$ system where the capacity levels are ordered, $C_1 \leq C_2$. This policy dictates that optimal echelon base-stock levels exist and both installations will attempt to reach these levels if possible, although C_1 acts to limit the entire system and the higher installation will never stock any more than C_1 , since the lower installation can never process any more than this amount in a single period.

Assembly Systems

Assembly systems combine multiple parts into a final assembled product. In this section, the optimal inventory policies in assembly systems facing uncertain market demand are described. Such systems are commonplace in practice, where parts and modules from adjacent installations are combined into sub-assemblies, which are themselves combined into a final assembled product. The product’s bill of materials (BOM) specifies the quantity and type of part and sequence of assembly which constitutes the final assembled product. Analyzing the management of inventory within an assembly system facing uncertain demand and with deterministic stationary arbitrary delivery lead times (assumed to be an integer multiple of the period) between installations is considered here.

As before, we consider an objective of minimizing the discounted expected system-wide costs. For the purposes of illustration, we will consider a system where each installation stocks a single part (without loss of generality) which when combined with parts of other installations, results in a single assembly or subassembly. Rosling [19] demonstrated that under a “balanced inventory” condition, the inventory operation in any general assembly system can be reduced to an *equivalent serial system*, thus being able to utilize the optimal policy for a serial system (echelon base-stock) described above. The basic approach is for the system to account for potentially differing lead times for installations supplying an immediately downstream assembling installation. Each of these supplying installations will stock such that it can provide the same quantity to the assembler at the same time. Rosling [19] found that the *echelon lead times*, defined as the sum of all the lead times between the installation in question and the final assembler, determines the order of the installations in an equivalent serial system. The lead times in the equivalent serial system will simply be the differences of the echelon lead times from the assembly system. The intuition behind this is simply to find an equivalent distance from the market in terms of lead time. Once this transformation to the series system is achieved, the optimal echelon base-stock levels can be found using

the Clark and Scarf [9] approach, which will serve as the echelon base-stock levels in the assembly system.

Distribution Systems

Distribution systems consist of installations where there is at most a single upstream installation and potentially multiple downstream installations. In practice, they typically involve the movement of a finished good to warehouses and retail outlets, where they are sold to the market. When facing unknown demand, the optimal inventory policy is not known for general distribution systems, but some results are known for specific but commonly observed distribution systems. Most of the known results are for a single warehouse supplying parallel retailers, the focus of our attention in this section.

The echelon base-stock policies previously described also play a role in distribution systems. In the two-echelon system consisting of a single warehouse and multiple retailers, stocking decisions need to be made at all installations, but additionally it is possible that *allocation* decisions need to be made when scarce warehouse inventory needs to be distributed across needy retailers. Optimal results can be found when there are no differences between the retailers in terms of demands, lead times, and holding and stock-out costs, and these optimal policies can perform well when there are differences between the retailers. Federgruen [20] distinguishes between the models when inventory is held at the warehouse and when it is not. When no inventory is stocked at the warehouse, the total amount drawn by the retailers will equal the quantity ordered by the warehouse (in a previous period), but this is not necessarily so when some remnant stock may be left at the warehouse. For each of these warehouse with/without inventory models, Federgruen [20] describes a “relaxed” and a “restricted” model to provide lower and upper bounds of the optimal policy. The relaxed model for the warehouse without inventory model consists of allowing a negative value of the allocation to particular retailers, enabling a vast simplification of the formulation so that the sum of the individual retailer inventories replaces the individual quantities in the state

space. Allowing negative allocations amounts to assuming transshipment between retailers can be carried out (essentially) costlessly. When the retailers’ cost parameters are identical, the myopic (Newsvendor) solution is then optimal for the retailers and an echelon base-stock decision (simple base-stock or (s, S) if there is a fixed ordering cost) is optimal for the warehouse. The restricted approach consists of applying a specific but parsimonious order policy, such as following an echelon base-stock policy for the warehouse when only ordering in certain periods (e.g., every m periods). Similarly, particular allocation policies have been examined including the myopic (each retailer solves the Newsvendor) and cyclic allocation policies. Knowing that the optimal policy lies between these relaxed and restricted models on a system-wide cost basis, the gap between these approximations can give an idea of the degree of suboptimality of following these approaches, given that finding the true optimal policy is impractical. For the warehouse with inventory model, the relaxed approach (removing the nonnegativity constraint for retailer orders) with myopic retailer allocation results in an even better solution than for the warehouse without inventory model. Again, the relaxation and restriction approach with appropriate allocation policies in conjunction with echelon base-stock policies tends to perform well.

FURTHER SOURCES

Zipkin [21], Porteus [22], and Axsäter [23] serve as excellent references for inventory theory under stochastic demand. Excellent summaries of the literature exist in Federgruen [20], Axsäter [24], and Porteus [25].

MULTIMETHODOLOGY

JOHN MINGERS
Kent Business School,
University of Kent,
Canterbury, Kent, UK

Operations research developed during and after World War II. It was based on adopting a scientific approach toward decision making in organizations, and many specific techniques, usually quantitative or mathematical, were developed. However, by the 1970s and 1980s, practitioners had found that there were many situations, or perhaps aspects of situations, that could not be adequately represented by mathematical or computer-based modeling [1]. This led to the development of several new “softer” methods that took the human or subjective dimension of problem situations seriously, while still being rigorous and systemic. Examples of such methods are soft systems methodology (SSM) [2], cognitive mapping and journey making [3] (see *Cognitive Mapping and Strategic Options Development and Analysis (SODA)*), strategic assumption surfacing and testing (SAST) [4], strategic choice approach (SCA) [5], and critical systems heuristics (CSH) [6]. These are sometimes called *problem-structuring methods* [7] (see *Problem Structuring for Multicriteria Decision Analysis Interventions*) or more recently *qualitative OR*.

However, this plethora of methods, both hard and soft, led to difficulties in knowing which was the most appropriate one to use in a particular situation. To try and help with this issue, Jackson and Keys [8] developed a framework of “problem contexts”—the *system of systems methodologies*. This proposed that there were two primary dimensions to be considered in looking at the context of a problem—the degree of agreement among participants about the nature of the problem and the objectives to be pursued, and the degree of complexity of the problem. The first

dimension was split into three possibilities: *unitary* situations, where there was a high degree of consensus among participants; *pluralistic* situations, where there were different viewpoints or stakeholder interests but a negotiated agreement was seen as possible; and *coercive* situations, where there were significant disagreements that could only be resolved by the exercise of power by one party over another. The second dimension was split into *simple* and *complex*, although in reality this is really a continuum. Simple problems are reasonably well defined and the nature of the problem is clear, although there could be a high degree of combinatorial difficulty. Complex problems are hard to define, difficult to bound, and resist analysis. They have also been called *wicked problems* by Rittel and Weber [9].

This yielded six cells into which OR methods or methodologies could be placed, thus giving guidance on which one should be used in a particular context. For example, traditional, hard, mathematical OR models were most suitable in simple unitary contexts, where the nature of the problem was clear and there was agreement regarding the objectives. System dynamics was a possibility in complex unitary contexts involving dynamic, feedback-driven situations. SSM was seen as appropriate for complex pluralistic contexts in which there were significant differences in viewpoints. This framework was later developed into a methodology known as *total systems intervention* (TSI) [10].

Although a step forward, the framework had several limitations [11]. In particular, it assumed that problems could be clearly identified as being of a particular type; that methods fitted neatly into the cells; and therefore a practitioner just needed to choose an appropriate method to deal with their particular type of problem. While it may sometimes be the case that a very well-defined problem requires a clear and unique method of solution, it can be argued that generally problem situations within real-world organizations are complex with

several dimensions—technical, social, and personal. Also, projects go through several phases—from initial discovery and problem shaping, through analysis, to eventual implementation—and different methods may be helpful at certain stages and not others. Finally, methods themselves may be used in different ways—a system dynamics model, for example, could be seen as a model of objective reality, or a model of an individual's personal mental model.

This leads to the idea of using multiple methods—*multimethodology* [12,13]—that is, deliberately seeking to combine together a range of methods, perhaps both soft and hard, in order to match the richness of the problem situation and to deal effectively with the different stages of a project. In doing this, practice was ahead of theory: a survey of SSM users [14] unexpectedly found SSM routinely combined with other methods, and Ormerod [15–17] has documented a number of sophisticated multimethodology interventions from the early 1990s.

ARGUMENTS FOR MULTIMETHODOLOGY

Adopting a particular method or methodology is like viewing the world through an instrument such as a telescope, an X-ray machine, or an electron microscope. Each reveals certain aspects of the situation but is completely blind to others. Although they may be pointing at the same place, each instrument produces a different, and sometimes seemingly incompatible, representation. Thus, in adopting only one method one is inevitably gaining only a limited view of a particular problem situation. For example, mathematical programming (see *An Introduction to Linear Programming*) focuses on factors that can be quantified and relationships (often assumed to be linear) between them; discrete event simulation (see *Introduction to Discrete-Event Simulation*) looks at the frequency of occurrence of particular events; SSM models notional systems of human activity within a social context; and critical systems heuristics (CSH) draws attention to the power of experts in defining boundaries and problems.

It has been suggested [18] that there are three fundamental dimensions of importance—the material world, the social world, and the personal world. Thus, any real-world situation into which we are intervening or researching will be a complex interaction of substantively different elements. There will be aspects that are relatively hard and observer-independent, particularly material and physical processes, which we can observe and model. There will be aspects that are socially constituted, dependent on particular cultures, social practices, languages, and power structures, which we must come to share and participate in. Finally, there will be aspects that are individual, such as beliefs, values, fears, and emotions, which we must try to express and understand. An effective intervention should therefore combine methods that address all three domains.

The second argument is that an OR project is not a discrete event but a process that has phases or different types of activities predominating at different times. Particular methodologies and techniques are more useful for some phases than others and so a combination of approaches may be necessary to provide a comprehensive outcome. The following four phases can be identified:

- *Appreciation* of the situation as experienced by the practitioners involved and expressed by participants in the situation. This involves an initial identification of the concerns to be addressed; conceptualization and design of the study; and the production of basic data using methods such as observation, interviews, experiments, surveys, or qualitative approaches.
- *Analysis* of the information produced so as to be able to understand and explain why the situation is as it is. What are the underlying structures and constraints that shape the situation? This involves analysis methods appropriate to the goal(s) of the intervention and the information produced in the first stage.
- *Assessment* of possible explanations and of potential changes to the situation. This involves the generation of

alternative arrangements or courses of action and an evaluation of their desirability and feasibility.

- *Action* to bring about changes, if necessary or desired, or to report on and disseminate the results if the project is simply research.

Put crudely, these phases cover: What is happening? Why it is happening? How could the situation be changed? And, what shall we do? At the beginning of an intervention, especially for an agent from outside the situation, the primary concern is to gain as rich an appreciation of the situation as possible. Note that this cannot be an “observer-independent” view of the situation “as it really is.” It is conditioned by the researchers’ previous experiences and their access to the situation. The next activity is to begin to analyze why the situation is as it appears, to understand the history that has generated it, and the particular structure of relations and constraints that maintain it. Next, in cases where changes to the situation are sought, consideration must be given to ways in which the situation could be changed. This means focusing attention away from how things are, and considering the extent to which the structures and constraints can be changed within the general limitations of the intervention. Finally, action must be undertaken that will effectively bring about agreed changes. It should be emphasized that these activities are not discrete stages that are enacted one by one; rather, they are aspects of the intervention that need to be considered throughout, although their relative importance will differ as the project progresses.

It is clear that the wide variety of methods and techniques available do not all perform equally well in all these activities. Some brief examples are as follows: collecting data, administering questionnaires and surveys, developing rich pictures and cognitive maps, and employing the 12 CSH questions, all these contribute toward finding out about the different aspects of a particular situation (Appreciation), whereas building simulation or mathematical models, constructing root definitions and conceptual models

(SSM), using role-playing and gaming, or undertaking participant observation help in understanding why the situation is as it is (Analysis) and in evaluating other possibilities (Assessment).

MULTIMETHODOLOGY IN ACTION

Multimethodology, when in use, is a creative process of design based on competence in a range of methods. Each project or intervention is seen as a unique situation (although it has features in common with others) for which a particular combination of methods, or parts of methods, needs to be constructed. This is an on-going process throughout the project, as events occur and the situation evolves. The general process can be described as follows:

Reflection:

- *review* the current situation;
- *determine* which areas of the problem situation currently need to be addressed.

Design:

- *understand* what methods or techniques could possibly be useful;
- *choose* the most appropriate method to use in relation to the project context as a whole.

There are several general approaches to combining together methods and methodologies, and more guidance, both for practical interventions and for research, can be found in Mingers [19], Mingers [20], Jackson [21], and Midgley [22]. The idea of mixed methods is not just confined to OR but is now also common in social science research in general [23,24]

Munro and Mingers [25] undertook a survey of examples of multimethodology in practice, which showed that the examples were common and successful. Drawing from this survey, and from other sources, we can highlight particular combinations of methods that have been shown to work well together.

- Cognitive mapping is a general approach to capturing peoples' thinking about particular complex issues and as such is compatible with many other methods. It is particularly synergistic with systems dynamics (SD), as a map can be converted into an SD model; it is also often used in the early stages of SSM to enhance the appreciation of the problem situation; and it has been used with Delphi, scenarios, and strategic choice.
- SSM itself is very flexible and can be used to structure the whole intervention. It is often used as the dominant method augmented by other techniques. It has been used extensively in information systems development [26], both as a "front-end" to harder, structured systems analysis techniques, and as the controlling method throughout the systems development.
- Strategic choice can also be combined with SSM, particularly in the later stages of an intervention when decisions about, and commitments to, action are being negotiated.
- The viable systems model (VSM) [27] is useful when there is organizational change as it focuses attention on the necessary structural and communication features of an effective organization. It has regularly been used with SSM and CSH.
- It is also interesting to see techniques being used out of their usual setting, such as a hard technique being used in a soft way. For example, quantitative models such as mathematical programming or system dynamics (SD) are usually assumed to be objective, that is, models of *independent reality*. However, it is possible to see them as subjective, as models of *particular concepts or views of possible realities*. They can then be used within, say, SSM, to help articulate a debate among rival positions.

EXAMPLES

To illustrate the approach, we note two examples that mix together hard and soft approaches. The first is a combination of mathematical modeling, in this case data envelopment analysis (DEA), and SSM [28]. The project was to develop a set of indicators to be used in evaluating the performance of the 80 research institutes of the Chinese Academy of Sciences (CAS). The initial plan was to use DEA to compare the performance of the institutes. However, it proved very difficult to get agreement about the real purpose of the evaluation and which indicators to use. At this point, SSM was brought in to facilitate a debate between the different participants, and provide a structured method for generating appropriate indicators. The combination was found to be very successful and has now been developed into a general methodology for performance evaluation in public sector organizations [29].

In the second example, cognitive mapping was combined with SD and statistical analysis in order to model how delays had occurred within a major construction project—the Channel Tunnel [30]. A contractor was suing a client for the extra costs caused by late design approvals and specification changes. A system dynamics model was required that could be used in court to support the claim and quantify the extent of the costs. The complexity of the project and the various different groups and professions involved made it very difficult to begin the construction of an SD model. So the project began by using cognitive mapping to capture the different viewpoints of the senior staff. A single group map was agreed upon with those concerned. This group map was maintained and updated throughout the project forming invaluable documentation "behind" the SD model. This map was then converted into an influence diagram by picking out the main (98) feedback loops. These were often interrelated in clusters.

The model was decomposed into two main areas: the design and acquisition-of-resources processes. From these, the SD models were developed, first structurally and

then in a quantified form. Inevitably, there were many problems with data availability and reliability. Much spreadsheet work was involved. Often inconsistencies were discovered. These had to be resolved by further discussion and development of both the cognitive map and the SD model. The SD model became very large (over 350 variables) and rather opaque, yet it needed to be clearly understood by a judge and barristers. This was helped by the COPE model (software for cognitive mapping), which was much easier to understand (as it was text based) but still mapped onto the SD one. The final result was developed through a constant interaction between the two. In the end, neither model actually appeared in court as the case was settled by agreement after a detailed audit of the models by both sides.

MULTISTAGE (STOCHASTIC) GAMES

Shapley introduced the concept of stochastic games in his seminal paper [1] in 1953. In a stochastic game, players play noncooperatively and simultaneously in stages (discrete points in time). Shapley defined two-person zero-sum (TPZS) discounted finite stochastic games as a generalization of matrix games or two-person zero-sum (TPZS) games. Refer the section titled “Two-Person Zero-Sum (TPZS) Games” for TPZS Games. A TPZS discounted finite stochastic game consists of a finite number of states, finite sets of actions of the players, a payoff matrix in each state, and transition probabilities from each state to every other state, for every pair of actions of the players. As in the case of TPZS games, one of the players chooses rows and the other player chooses columns. We shall assume that the row chooser is the maximizer and the column chooser is the minimizer. Given a starting state, the players simultaneously choose actions resulting in an immediate payoff (the corresponding entry in the payoff matrix) that is paid to the row chooser by the column chooser and the game moves to a new state depending on the transition probabilities. Now, the players choose actions in the new state, resulting in a payoff in that state, and so on. At each time period, these payoffs are successively discounted by a factor $\beta \in [0, 1)$ and these discounted payoffs are accumulated over the infinite horizon. Starting at different states, we obtain different accumulated discounted payoffs. The aim of the row chooser is to maximize these accumulated discounted payoffs, and the aim of the column chooser is to minimize the same. Strategies of players are probability

distributions over their action sets, at each time period.

Shapley originally defined discounted stochastic games as stochastic games with positive stop probabilities. That is, given any state, the probability that the game stops is positive. It follows that the game stops with a probability 1 after a finite number of steps. It is easy to see that “discounted stochastic games” and “stochastic games with positive stop probabilities” are equivalent. Gillette [2,3] introduced stochastic games with zero stop probabilities or equivalently, stochastic games with undiscounted (or limiting average) payoffs. Undiscounted payoffs are *lim sup* or *lim inf* of accumulated average payoffs over the infinite run.

As we discussed above, zero-sum stochastic games can be considered as a generalization of TPZS games. Nonzero-sum stochastic games are a generalization of one shot noncooperative strategic-form (NCSF) games. Concepts of von Neumann’s minimax value (see *Saddlepoints and von Neumann Minimax Theorem*) and Nash equilibria [4] (see *Nash Equilibrium (Pure and Mixed)*) can be extended to stochastic games as well. Stochastic games may also be considered as a generalization of Markov decision processes (MDPs) (see the section titled “Markov Decision Process (MDP)” in this encyclopedia) with two or more players whose payoffs and the transition probabilities depend on the choice of actions of the players. Stochastic games are a generalization of repeated games as well. Repeated games are stochastic games with just one state.

Following is an example of a zero-sum stochastic game.

Example 1. The following game has two states s_1 and s_2 . Both players have two actions in state s_1 . In s_2 , player 1 (the row player/ maximizer) has three actions and player 2 (the column player/ minimizer) has two actions. The payoffs and transition probabilities are given below.

$$s_1 : \begin{bmatrix} 2 & 1 \\ (\frac{1}{4}, \frac{3}{4}) & (0, 1) \\ 0 & 3 \\ (\frac{1}{4}, \frac{3}{4}) & (0, 1) \end{bmatrix}, s_2 : \begin{bmatrix} 0 & 2 \\ (\frac{1}{2}, \frac{1}{2}) & (\frac{1}{2}, \frac{1}{2}) \\ 2 & 1 \\ (1, 0) & (1, 0) \\ 3 & 0 \\ (0, 1) & (0, 1) \end{bmatrix}.$$

In each row, the entries on the top are the payoffs. The entries below the payoffs (enclosed in parentheses) are the transition probabilities to states s_1 and s_2 , respectively. For example, in state s_1 , if the players choose row 1 and column 1, the row chooser gets an immediate payoff of 2 from the column chooser. The game remains in state s_1 with probability $\frac{1}{4}$ and transitions to state s_2 with probability $\frac{3}{4}$.

We formally define two-player finite stochastic games in the following section.

TWO-PERSON FINITE STOCHASTIC GAMES

In this section, we define TPZS and two person nonzero-sum finite stochastic games with discounted as well as undiscounted payoffs. We define stationary strategies, Markov strategies, and behavioral (or history-dependent) strategies. For zero-sum stochastic games, we define optimal strategies and optimal value, and we state Shapley's theorem for the discounted case. We define Nash equilibrium strategies and payoffs for the nonzero-sum case.

Definition 1 [Two-player, finite stochastic game]. A two-player, finite state space, finite action space stochastic game consists of

1. Two players P_1 and P_2 . We shall sometimes refer to them just as players 1 and 2.
2. A finite, nonempty set of states, $S = \{1, 2, \dots, N\}$.
3. For each state $s \in S$, finite, nonempty sets $A_1(s) = \{1, 2, \dots, m_1(s)\}$ and $A_2(s) = \{1, 2, \dots, m_2(s)\}$ of actions for players P_1 and P_2 , respectively. Without loss of generality, we may assume $A_1(s) = A_1$

and $A_2(s) = A_2$, $\forall s \in S$. (This assumption is only for ease of analysis and may be dropped).

4. Immediate rewards $r_1(s, i, j)$ for player 1 and $r_2(s, i, j)$ for player 2, where $s \in S, i \in A_1, j \in A_2$, when the game is in state s and the players choose actions i and j , respectively. If $r_2 = -r_1$, then, we have a zero-sum game. Otherwise, the game is a nonzero-sum game. We will use r in place of r_1 in case of zero-sum games. We will denote the matrix of immediate rewards in state s by $R_1(s)$ and $R_2(s)$ for players 1 and 2, respectively (and by $R(s)$ in case of zero-sum games).
5. Transition probabilities $(q(s'|s, i, j) : (s, s') \in S \times S, i \in A_1, j \in A_2)$ where $q(s'|s, i, j)$ is the probability of transition from state s to state s' given that players 1 and 2 choose actions $i \in A_1, j \in A_2$, respectively. These transition probabilities constitute the "law of motion" of the game. We will use $q(s, i, j)$ to denote the corresponding probability distribution. Given $i \in A_1, j \in A_2$, we denote the $N \times N$ transition matrix by $Q(i, j)$.

The game proceeds as follows. Given a starting state $s_0 \in S$, the players simultaneously choose actions $i_0 \in A_1$ and $j_0 \in A_2$, resulting in payoffs of $r_1(s_0, i_0, j_0)$ and $r_2(s_0, i_0, j_0)$ to players 1 and 2, respectively. The game moves to a new state s_1 according to the law of motion $q(s_0, i_0, j_0)$, and the players choose actions $i_1 \in A_1$ and $j_1 \in A_2$ resulting in payoffs of $r_1(s_1, i_1, j_1)$ and $r_2(s_1, i_1, j_1)$, and so on.

In general, strategies can depend on complete histories of the game until the current stage. Such strategies are called *behavioral strategies*. *Markov (or memoryless) strategies* are behavioral strategies that depend only on the current state and the current stage (or time period). *Stationary strategies* are a simpler class of strategies, which depend only on the current state s and not on how s was reached. In other words, stationary strategies are time-independent Markov strategies. For

discounted finite stochastic games, it suffices to look at stationary strategies.

For player 1, a stationary strategy f is a function from S to P_{A_1} , where S is the state space and P_{A_1} is the set of probability distributions on player 1's action set A_1 . Similarly, we define a stationary strategy g for player 2 as a function from S to P_{A_2} . Alternatively, we can look at f as an N -tuple of probability distributions from P_{A_1} , one distribution per state. In other words, $f \in P_{A_1}^N$ where N is the number of states. Similarly $g \in P_{A_2}^N$. *Pure stationary strategies* are simply a set of actions, one per state.

Remark. Strategies for the players determine the distribution of the stochastic process of states and actions.

In the following definitions, $r_t^{(1)}(s_0, f, g)$ and $r_t^{(2)}(s_0, f, g)$ are the expected immediate rewards at the t th stage, to players P_1 and P_2 , respectively.

Definition 2 [β -discounted payoffs]. In the nonzero-sum case, given an initial state s_0 , a pair of stationary strategies (f, g) of players 1 and 2, and a discount factor $\beta \in (0, 1)$, we define β -discounted payoffs as follows:

$$I_\beta^{(1)}(f, g)(s_0) = \sum_{t=0}^{\infty} \beta^t r_t^{(1)}(s_0, f, g) \text{ for } P_1 \text{ and} \quad (1)$$

$$I_\beta^{(2)}(f, g)(s_0) = \sum_{t=0}^{\infty} \beta^t r_t^{(2)}(s_0, f, g) \text{ for } P_2. \quad (2)$$

In the zero-sum case,

$$I_\beta^{(1)}(f, g)(s_0) = -I_\beta^{(2)}(f, g)(s_0). \quad (3)$$

(We shall denote $I_\beta^{(1)}$ by I_β in this case).

Definition 3 [Undiscounted payoffs].

In the nonzero-sum case, given an initial state s_0 , and a pair of stationary strategies (f, g) , of players 1 and 2, we define the

undiscounted (or limiting average) payoffs as follows:

$$\Phi^{(1)}(f, g)(s_0) = \liminf_{T \uparrow \infty} \left[\left(\frac{1}{T+1} \right) \times \sum_{t=0}^T r_t^{(1)}(s_0, f, g) \right] \text{ for } P_1 \text{ and} \quad (4)$$

$$\Phi^{(2)}(f, g)(s_0) = \liminf_{T \uparrow \infty} \left[\left(\frac{1}{T+1} \right) \times \sum_{t=0}^T r_t^{(2)}(s_0, f, g) \right] \text{ for } P_2. \quad (5)$$

In the zero-sum case,

$$\Phi^{(1)}(f, g)(s_0) = -\Phi^{(2)}(f, g)(s_0). \quad (6)$$

(We shall denote $\Phi^{(1)}$ by Φ in this case).

We write $\Gamma_\beta = (S, A_1, A_2, r_1, r_2, q, \beta)$ ($\Gamma = (S, A_1, A_2, r_1, r_2, q)$) to denote a β -discounted (undiscounted) nonzero-sum stochastic game with set of states S , sets of actions A_1 and A_2 , and rewards r_1 and r_2 as defined above. Whenever $r_1 = -r_2$ ($=r$, say), we have a zero-sum game.

Definition 4 [Optimal strategies and optimal value]. A pair of stationary strategies (f^*, g^*) is optimal in the zero-sum discounted case, if for all $s \in S$

$$I_\beta(f, g^*)(s) \leq I_\beta(f^*, g^*)(s) \leq I_\beta(f^*, g)(s) \quad \forall f \in P_{A_1}^N, \forall g \in P_{A_2}^N. \quad (7)$$

(assuming that player 1 is the maximizer and player 2 is the minimizer).

In other words, $I_\beta(f^*, g^*)(s) = \inf_g [I_\beta(f^*, g)(s)] = \sup_f [I_\beta(f, g^*)(s)] \forall s \in S$.

Shapley [1] proved the existence and uniqueness (across all pairs of optimal strategies (f^*, g^*)) of the optimal value vector $I_\beta(f^*, g^*)$, denoted by v_β . That is, when the game starts at state $s \in S$, $v_\beta(s)$ is unique and this is true for all $s \in S$. That is,

$$\begin{aligned} v_\beta(s) &= I_\beta(f^*, g^*)(s) = \sup_f \inf_g [I_\beta(f, g)(s)] \\ &= \inf_g \sup_f [I_\beta(f, g)(s)] \forall s \in S. \end{aligned}$$

Note that there may be different pairs of optimal strategies (f^*, g^*) .

A pair of stationary strategies (f^*, g^*) is optimal for the undiscounted zero-sum game, if for all $s \in S$

$$\Phi(f, g^*)(s) \leq \Phi(f^*, g^*)(s) \leq \Phi(f^*, g)(s) \quad \forall f \in P_{A_1}^N, g \in P_{A_2}^N. \quad (8)$$

(assuming player 1 is the maximizer and player 2 is the minimizer).

Mertens and Neyman [5] proved the existence and uniqueness of the optimal value vector in the undiscounted case. Both players may not have optimal strategies though, as we shall see soon. We write v to denote the optimal value vector Φ of the undiscounted stochastic game, which is a function of the initial state s . That is, for all $s \in S$, $\Phi(s) = \sup_f \inf_g [\Phi(f, g)(s)] = \inf_g \sup_f [\Phi(f, g)(s)]$.

Definition 5 [Nash equilibrium]. A pair of stationary strategies (f^*, g^*) constitutes a Nash equilibrium in the discounted case if $\forall s \in S$

$$I_\beta^{(1)}(f^*, g^*)(s) \geq I_\beta^{(1)}(f, g^*)(s) \text{ for each } f \in P_{A_1}^N \text{ and} \quad (9)$$

$$I_\beta^{(2)}(f^*, g^*)(s) \leq I_\beta^{(2)}(f^*, g)(s) \text{ for each } g \in P_{A_2}^N. \quad (10)$$

(assuming that both players want to maximize their payoffs).

Similarly, in the undiscounted case, a pair of stationary strategies (f^*, g^*) constitutes a Nash equilibrium, if $\forall s \in S$

$$\Phi^{(1)}(f^*, g^*)(s) \geq \Phi^{(1)}(f, g^*)(s) \text{ for each } f \in P_{A_1}^N \text{ and} \quad (11)$$

$$\Phi^{(2)}(f^*, g^*)(s) \leq \Phi^{(2)}(f^*, g)(s) \text{ for each } g \in P_{A_2}^N. \quad (12)$$

(assuming that both players want to maximize their payoffs).

[We can extend these definitions to the n -player case too ($n > 2$)].

Now, we discuss Shapley's theorem [1] regarding the existence of optimal value and optimal stationary strategies in zero-sum discounted finite stochastic games. Informally, the value of the stochastic game starting at state s is the value of the matrix game obtained by adding to the immediate payoffs at s , the optimal expected discounted rewards from the next time period onwards. This leads to a system of equations, solving which we obtain the value vector. We formally state Shapley's theorem below.

Theorem 1 [Shapley [1]] . A two-player zero-sum discounted stochastic game $\Gamma_\beta = (S, A_1, A_2, r, q, \beta)$ has an optimal value vector v_β which is the unique solution of the following system of equations

$$v(s) = \text{val}[R(s, v)]$$

for all $s \in S$, where $R(s, v)$ is the auxiliary matrix game with (i, j) th entry $r(s, i, j) + \beta \sum_{s' \in S} q(s' | s, i, j) v(s')$ and $\text{val}[R(s, v)]$ is the minimax value of the matrix game.

For each state $s \in S$, if $(f^*(s), g^*(s))$ is a pair of optimal strategies of the matrix game $R(s, v_\beta)$, then (f^*, g^*) is a pair of optimal strategies for the discounted stochastic game Γ_β , where $f^* = (f^*(1), f^*(2), \dots, f^*(N))$ and $g^* = (g^*(1), g^*(2), \dots, g^*(N))$.

The proof of Shapley's theorem follows from the fact that $L : R^N \rightarrow R^N$ defined by $L(v)(s) = \text{val}[R(s, v)]$ for all $v \in R^N, s \in S$, is a contraction map (as $\beta \in [0, 1)$). Hence, by Banach's fixed point theorem, L has a unique fixed point. The unique solution of $L(v) = v$ gives the optimal value vector v_β of the stochastic game. We implicitly use the fact that a strategy is optimal versus all strategies if it is optimal versus stationary strategies.

In the following example, we illustrate the use of Shapley's theorem in solving a zero-sum discounted stochastic game.

Example 2. The game has two states s_1 and s_2 . Both players have two actions in s_1

and one action each in s_2 . The payoffs and transition probabilities are given below:

$$s_1 : \begin{bmatrix} 2 & 0 \\ (0, 1) & (0, 1) \\ 0 & 2 \\ (1, 0) & (0, 1) \end{bmatrix}, \quad s_2 : \begin{bmatrix} 0 \\ (0, 1) \end{bmatrix}.$$

Here, we represent the (i, j) th entry in the matrix corresponding to state s_k as follows:

$$\begin{bmatrix} r(s_k, i, j) \\ (q(s_1|s_k, i, j), q(s_2|s_k, i, j)) \end{bmatrix}.$$

Using Shapley's theorem, optimal value of this stochastic game starting at state s_1 is

$$v_\beta(1) = \text{val} \begin{bmatrix} 2 + \beta v_\beta(2) & 0 + \beta v_\beta(2) \\ 0 + \beta v_\beta(1) & 2 + \beta v_\beta(2) \end{bmatrix}. \quad (13)$$

For brevity, we shall write v_s in place of $v_\beta(s)$. Let $\beta = \frac{1}{2}$ be the discount factor. Then

$$v_1 = \text{val} \begin{bmatrix} 2 + \frac{1}{2}v_2 & \frac{1}{2}v_2 \\ \frac{1}{2}v_1 & 2 + \frac{1}{2}v_2 \end{bmatrix}. \quad (14)$$

In state s_2 , both players have no choice but to play their only actions available. Further, s_2 is an absorbing state. In other words, once the game reaches s_2 , it remains in s_2 forever. Therefore, value of the game starting at state s_2 is $v_2 = 0$.

It is easy to check that the auxiliary matrix game corresponding to state 1 has no pair of pure optimal strategies. (That is, the players cannot play optimally by choosing actions with probability 1, and they must choose mixed strategies, or probability distributions over their respective action sets). Therefore, we can use Kaplansky's theorem [6] to solve the game.

We state Kaplansky's theorem below and omit the proof.

Theorem 2 [Kaplansky [6]]. *Given a 2×2 matrix game*

$$M = \begin{bmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{bmatrix}$$

that does not have a pure optimal strategy pair, the value of the game is

$$\text{val}(M) = (m_{11}m_{22} - m_{21}m_{12}) / (m_{11} + m_{22} - m_{12} - m_{21}).$$

Using Kaplansky's theorem, we get

$$v_1 = 4 / (4 - \frac{1}{2}v_1)$$

solving which we get

$$v_1 = 4 \pm 2\sqrt{2}.$$

$v_1 = 4 + 2\sqrt{2}$ is not possible as $v_1 \leq 4$ (since, at each stage of the game, even if player 1 gets the maximum possible payoff of 2, $v_1 = 2 + \beta v_1$ which gives $v_1 = 4$).

Therefore, $v_1 = 4 - 2\sqrt{2}$.

For nonzero-sum n -person (or multi player) discounted stochastic games, existence of equilibrium strategies was shown by Fink [7], Takahashi [8], Rogers [9], and Sobel [10]. We state the theorem below for the two-person case, and the proof uses Kakutani's fixed point theorem.

Theorem 3. *Every two-person nonzero-sum discounted stochastic game has a pair of stationary strategies (f^*, g^*) of the players that constitutes a Nash equilibrium. Assuming that the players are maximizers, for each $s \in S$ and for all strategies f of P_1 and g of P_2*

$$I_\beta^{(1)}(f^*, g^*)(s) = \sup_f [I_\beta(f, g^*)(s)] \text{ and}$$

$$I_\beta^{(2)}(f^*, g^*)(s) = \sup_g [I_\beta(f^*, g)(s)].$$

As in the case of MDPs (refer articles in the section titled "Markov Decision Processes" in this encyclopedia), analyzing the undiscounted case (see articles in the section titled "Average Reward Criterion" in this encyclopedia) is more challenging than the discounted case (see articles in the section titled "Total Expected Discounted Reward Criterion" in this encyclopedia) for stochastic games as well. Gillette [3] gave an example

of an undiscounted zero-sum stochastic game, where one of the players does not have a stationary optimal strategy. In 1968, Blackwell and Ferguson [11] showed that this game (they call it “the big match”) does not admit an optimal strategy for one of the players, even when behavioral strategies are allowed. We state this example below and refer the reader to the paper by Blackwell and Ferguson [11] for details.

Example 3 [The big match (with undiscounted payoffs)]. The game has three states s_1 , s_2 , and s_3 . States s_2 and s_3 are absorbing, that is, once the game reaches these states, it remains there forever. The payoffs and transition probabilities are given below.

$$s_1 : \begin{bmatrix} 1 & 0 \\ (1, 0, 0) & (1, 0, 0) \\ 0 & 1 \\ (0, 1, 0) & (0, 0, 1) \end{bmatrix},$$

$$s_2 : \begin{bmatrix} 0 \\ (0, 1, 0) \end{bmatrix},$$

$$s_3 : \begin{bmatrix} 1 \\ (0, 0, 1) \end{bmatrix}.$$

Player 1 tries to maximize the undiscounted payoff and player 2 tries to minimize the same.

It is easy to see that $v_2 = 0$ and $v_3 = 1$.

Further, $v_1 = \frac{1}{2}$ and in state 1, it is optimal for player 2 to play column 1 with probability $\frac{1}{2}$ and column 2 with probability $\frac{1}{2}$. However, player 1 does not have exact optimal strategies. (But for every $\epsilon > 0$, player 1 has a behavioral strategy that fetches her or him $(\frac{1}{2} - \epsilon)$).

Though optimal strategies may not exist for both players, every zero-sum undiscounted stochastic game has a value as shown by Mertens and Neyman [5]. We state this theorem below.

Theorem 4 [Mertens and Neyman [5]]. *Every zero-sum undiscounted stochastic game has a (unique optimal) value. That is,*

$$v(s) = \Phi(s) = \sup_f \inf_g [\Phi(f, g)(s)] \\ = \inf_g \sup_f [\Phi(f, g)(s)].$$

Further, the players have ϵ -optimal strategies (not necessarily stationary). That is, for all $\epsilon > 0$, there exists a pair of strategies $(f_\epsilon^, g_\epsilon^*)$ of players 1 and 2, such that for all $s \in S$ and for strategies f and g of players 1 and 2, respectively,*

$$\Phi(f, g_\epsilon^*)(s) - \epsilon \leq \Phi(s) \\ = v(s) \leq \Phi(f_\epsilon^*, g)(s) + \epsilon.$$

The proof of the above theorem uses a result of Bewley and Kohlberg [12], and we refer the reader to Refs 5 and 12 for details.

On the one hand, significant research has been done in proving such existence results. Such existence results have also been extended to stochastic games with infinite state space and infinite action space for the discounted zero-sum and nonzero-sum cases as well as to the undiscounted zero-sum case. (Refer Maitra and Parthasarathy [13], Sobel [14]). Maitra and Sudderth [15–18] proposed an alternative proof of the existence of value in the finite, undiscounted, zero-sum case, which extends to the case when the state space is uncountable as well. For nonzero-sum undiscounted finite stochastic games, Vieille [19,20] proved the existence of ϵ -equilibrium strategies for the two-player case. The problem remains open for undiscounted stochastic games with three or more players.

On the other hand, computing the optimal value and optimal strategies (in the zero-sum case), and a Nash equilibrium (in the nonzero-sum case) has triggered a flurry of research activity, computational as well as theoretical. In general, solving a discounted stochastic game may not be as easy as in Example 2 above, either. Solving the system of equations as a result of Shapley’s theorem does give us the value vector but this system of equations

may not be easy to solve. However, we can compute approximate Nash equilibria by using iterative Newton–Raphson type procedures (Pollatschek and Avi-Itzhak [21]). The basis of such procedures is the fact that Shapley’s theorem can be viewed as computing the fixed point of the operator $L : R^N \rightarrow R^N$ defined by $L(v)(s) = \text{val}[R(s, v)]$ as we discussed earlier.

Even in Example 2 above, as v_1 is irrational, it is not possible to design a finite arithmetic step exact algorithm. However, some classes of stochastic games are guaranteed to have (at least) one rational solution, given rational inputs, and this is the focus of the next section.

ORDERFIELD PROPERTY OF STOCHASTIC GAMES

In 1950, Weyl [22] showed that matrix games possess the orderfield property. In other words, given payoffs from an ordered field, there exists a pair of optimal strategies whose coordinates lie in the same ordered field. It follows that the optimal value lies in the same ordered field as well. Bimatrix games (two-person NCSF games) also have the orderfield property when restricted to the rational field. Nash [4], in his seminal paper in 1951, gave an example of a three-player noncooperative game with rational payoffs but a unique irrational equilibrium. Unlike matrix games, stochastic games may not possess the orderfield property even in the discounted zero-sum case as pointed out by Shapley [1]. Parthasarathy and Raghavan [23] provide an explicit example. Example 2 above is another example of such a game that does not possess the orderfield property.

In this article, whenever we talk of the orderfield property, we restrict ourselves to the field of rationals.

Definition 6 [Stochastic game with the orderfield property]. A zero-sum stochastic game with rational inputs [i.e., rational payoffs, rational transition probabilities, and a rational discount factor (in case of discounted stochastic games)] is said to possess the orderfield property if it has a pair

of rational optimal strategies (i.e., optimal strategies whose coordinates are rational). It follows that the value of the game is rational too.

A nonzero-sum stochastic game with rational inputs is said to possess the orderfield property if it has a pair of Nash equilibrium strategies whose coordinates are rational. It follows that the corresponding equilibrium payoffs are rational as well.

Some classes of stochastic games have been shown to satisfy the orderfield property owing to their special structures. As at least one rational solution is guaranteed for these games, there is hope for finding a finite arithmetic-step algorithm to solve them. Researchers have been successful in designing algorithms for some of these classes. Refer Filar *et al.* [24], Nowak and Raghavan [25], Raghavan and Syed [26,27], and Vrieze [28] for some of these algorithms. On the other hand, there are classes where the problem is open. For some classes of stochastic games, though algorithms for solving them are known, search is on for efficient algorithms to solve them. For example, there is no efficient algorithm (yet) to solve switching control (SC) stochastic games.

We describe some classes of stochastic games that are known to possess the orderfield property. We refer the reader to a survey by Raghavan and Filar [29], a survey by Mohan *et al.* [30] and a survey by Raghavan [31] for more details on these classes and on algorithms for solving some of them.

Definition 7. Stochastic games with perfect information (Shapley [1]) are stochastic games in which in every state, the action space of (at least) one of the players is a singleton. In other words, we can partition the set of states S into S_1 and S_2 , where S_1 is the set of player 1 states (where player 2 has just one action and hence no choice) and S_2 is the set of player 2 states (where player 1 has just one action).

Definition 8. One player control stochastic games (Parthasarathy and Raghavan [23]) are stochastic games in which only one of

the players controls the transitions. For example, when player 2 controls transitions, $q(s'|s, i, j) = q(s'|s, j) \forall i \in A_1, j \in A_2, s, s' \in S$.

Definition 9. Simple stochastic games (SSG) (Condon [32]) are stochastic games with reachability objectives and no immediate rewards. There are two special absorbing states, the 0-sink and the 1-sink. Player 1 (the maximizer) wins if the 1-sink is reached, player 2 wins otherwise. Leaving out these special sink states, we can partition the remaining states into S_1 , S_2 , and S_3 , where S_1 is the set of player 1 states, (where player 2 has just one action and hence no choice), S_2 is the set of player 2 states (where player 1 has just one action), and S_3 is the set of nature (or average) states where the players do not have a choice and nature chooses the next state according to some probability distribution.

Remark. SSGs form a subclass of perfect-information stochastic games where the transition probabilities are 0 or 1 for all action-pairs in all states, S_1 and S_2 are player 1 and player 2 states, respectively, and in S_3 , both players have just one action.

Definition 10. Switching control (SC) stochastic games (Filar [33]) are games where the law of motion is controlled by player 1 alone when the game is played in a certain subset of states and by player 2 alone when the game is played in other states. In other words, a switching control game is a stochastic game in which the set of states are partitioned into sets S_1 and S_2 where the transition probabilities are given by

$$q(s'|s, i, j) = q(s'|s, i), \quad \text{for all } s' \in S, s \in S_1, \\ i \in A_1, j \in A_2$$

$$q(s'|s, i, j) = q(s'|s, j), \quad \text{for all } s' \in S, \\ s \in S_2, j \in A_2, i \in A_1$$

Remark. Switching control stochastic games are a superclass of SSGs,

perfect-information stochastic games, and one-player control stochastic games.

Definition 11. Separable reward-state independent transition (SER-SIT) (Parthasarathy *et al.* [34]) games are stochastic games in which

1. The rewards can be written as the sum of a function that depends on the state alone and another function that depends on the actions alone. That is, $r(s, i, j) = c(s) + a(i, j)$ for all $s \in S, i \in A_1, j \in A_2$, for the zero-sum case. For the nonzero-sum case, $r_1(s, i, j) = c(s) + a(i, j)$ and $r_2(s, i, j) = d(s) + b(i, j)$ for P_1 and P_2 , respectively, for all states $s \in S$, and actions $i \in A_1, j \in A_2$.
2. The transitions are independent of the state from which the game transitions. That is, $q(s'|s, i, j) = q(s'|i, j)$ for all $i \in A_1, j \in A_2, s, s' \in S$.

Definition 12. Additive reward additive transition (ARAT) (Raghavan *et al.* [35]) games are stochastic games where

1. The reward function can be written as the sum of two functions, one depending on player 1 and the other on player 2. For the zero-sum case, $r(s, i, j) = r'(s, i) + r''(s, j)$, for all $i \in A_1, j \in A_2, s \in S$. We can similarly write down r_1 and r_2 in the case of nonzero-sum games.
2. The transition probabilities can be written as a sum of two functions, one depending on player 1 and the other on player 2. That is, $q(s'|s, i, j) = q_1(s'|s, i) + q_2(s'|s, j)$, $i \in A_1, j \in A_2, s, s' \in S$.

There are interesting examples of stochastic games that have the orderfield property and do not fall into any of the known classes. The big match with discounted payoffs is one such game.

Example 4. The big match with discounted payoffs has the orderfield property:

$$s_1 : \begin{bmatrix} 1 & 0 \\ (1, 0, 0) & (1, 0, 0) \\ 0 & 1 \\ (0, 1, 0) & (0, 0, 1) \end{bmatrix}, \quad s_2 : \begin{bmatrix} 0 \\ (0, 1, 0) \end{bmatrix},$$

$$s_3 : \begin{bmatrix} 1 \\ (0, 0, 1) \end{bmatrix}.$$

Using Shapley's theorem, the value of the stochastic game starting at state s_1 is

$$v_1 = \text{val} \begin{bmatrix} 1 + \beta v_1 & \beta v_1 \\ 0 & 1 + \frac{\beta}{1-\beta} \end{bmatrix}. \quad (15)$$

This auxiliary matrix game is completely mixed. Using Kaplansky's theorem, we get

$$v_1 = \frac{1}{2(1-\beta)} \text{ which is rational when } \beta \text{ is rational.}$$

Now, we show that there exists a pair of rational optimal strategies as well. Assuming the column chooser is the minimizer, $(\frac{1}{2}, \frac{1}{2})$ is optimal for the column chooser.

Now, let $(z, 1-z)$ be an optimal strategy for the row chooser. Then,

$$\begin{bmatrix} z & 1-z \end{bmatrix} \begin{bmatrix} 1 + \beta v_1 & \beta v_1 \\ 0 & 1 + \frac{\beta}{1-\beta} \end{bmatrix} = \begin{bmatrix} v_1 & v_1 \end{bmatrix}.$$

Using $v_1 = \frac{1}{2(1-\beta)}$, we get $z = \frac{1}{2-\beta}$.

In other words, $(\frac{1}{2-\beta}, \frac{1-\beta}{2-\beta})$ is optimal for the row chooser and this strategy is rational whenever β is rational.

In the next section, we discuss algorithms for solving some of the above classes of stochastic games.

ALGORITHMS FOR SOME CLASSES OF STOCHASTIC GAMES

Different algorithms have been proposed for solving classes of stochastic games. Some of these algorithms reduce these stochastic games to a linear program (LP) (refer the section titled "Linear Programming (LP)" in this encyclopedia), some of them reduce them to matrix or bimatrix games, some of them use policy-improvement techniques similar to those for MDPs (refer **Total Expected Discounted Reward MDPs: Policy Iteration Algorithm**), and others use linear complementarity problems (LCP). (For LCPs, refer to the book by Cottle *et al.* [36]). For related results on the orderfield property of stochastic games and algorithms for various classes, apart from the citations listed above, we refer the reader to Flesch *et al.* [37], Mohan *et al.* [38], Schultz [39], Syed [40], Thuijsman and Raghavan [41], and Vrieze *et al.* [42].

LP Formulation of Zero-Sum Discounted One Player Control Stochastic Games

Let player 2 be the controlling player. In other words, $q(s'|s, i, j) = q(s'|s, j)$ for all $i \in A_1, j \in A_2, s, s' \in S$.

Let β be the discount factor.

Without loss of generality, we may assume that the payoffs are nonnegative (hence, $v_\beta(s) \geq 0$ for all $s \in S$).

Solving this game is equivalent to solving the following LP as shown by Parthasarathy and Raghavan [23]:

$$\max \sum_{s=1}^N v_\beta(s) \quad (16)$$

subject to

$$\sum_{i \in A_1} (r(s, i, j) + \beta \sum_{s' \in S} q(s'|s, j) v_\beta(s')) f_i(s) \geq v_\beta(s)$$

$$\forall j \in A_2, \forall s \in S. \quad (17)$$

$$\sum_{i \in A_1} f_i(s) = 1 \quad \forall s \in S \quad (18)$$

$$f_i(s), v_\beta(s) \geq 0 \quad \forall s \in S. \quad (19)$$

Here, $f_i(s)$ is the probability with which player 1 plays action i in state s .

For zero-sum undiscounted one player control stochastic games, Vrieze [28] proposed an LP formulation. Zero-sum discounted as well as undiscounted SER-SIT games can be reduced to matrix games (refer Sobel [43] and Parthasarathy *et al.* [34]) (and matrix games can be reduced to LPs).

Solving Two-Player Nonzero-Sum SER-SIT Games via Reduction to Bimatrix Games

Two-player nonzero-sum discounted and undiscounted SER-SIT games can be solved by reducing them to bimatrix games (Sobel [43], Parthasarathy *et al.* [34]). We discuss the discounted case below.

Let Γ be the β -discounted SER-SIT game with transitions $q(s'|i, j)$ and rewards $r_1(s, i, j) = c(s) + a(i, j)$ and $r_2(s, i, j) = d(s) + b(i, j)$ for P_1 and P_2 , respectively.

Construct the bimatrix game (A, B) where A and B are the following $m_1 \times m_2$ matrices:

$$A = [a(i, j) + \beta \sum_{s' \in S} q(s'|i, j)c(s')], B = [b(i, j) + \beta \sum_{s' \in S} q(s'|i, j)d(s')]. \quad (20)$$

If (x^*, y^*) is a pair of equilibrium strategies for the bimatrix game (A, B) , then $((x^*, x^*, \dots, x^*), (y^*, y^*, \dots, y^*))$ is a pair of equilibrium strategies for the β -discounted SER-SIT game Γ .

For two-player nonzero-sum one player control stochastic games, Nowak and Raghavan [25] proposed solving the discounted case and the irreducible undiscounted case via bimatrix games. (By irreducible we mean that the transition matrix induced by any pure stationary strategy of the controlling player is irreducible).

A Policy-Improvement Algorithm for Solving Zero-Sum Discounted Perfect Information Stochastic Games

Given a zero-sum β -discounted perfect-information stochastic game Γ , Raghavan and Syed [27] proposed the following algorithm to find a pair of pure stationary optimal strategies (f^*, g^*) . The algorithm is a policy-improvement algorithm similar to

that of Blackwell [44] for MDPs. MDPs can be thought of as one-person perfect-information stochastic games and as the player has the same objective (to maximize reward, say) across all states, it is intuitively clear why policy improvement works. In the case of TPZS perfect-information stochastic games, the players have conflicting objectives: one wants to maximize in some states and the other wants to minimize in other states. Even in this case, as Raghavan and Syed [27] prove, policy improvement works. The basis of the proof is Shapley's [1] theorem that perfect-information stochastic games have pure stationary equilibria. Hence, we only need to find a pair of pure stationary strategies (f^*, g^*) such that $I_\beta(f, g^*) \leq I_\beta(f^*, g^*) = v_s \leq I_\beta(f^*, g)$ for all pure strategies f and g of players 1 and 2, respectively.

The outline of the algorithm is as follows. The players start with an arbitrary stationary strategy pair (f_0, g_0) and generate a sequence of improvements via lexicographic search. That is, P_1 first looks for an improvement in state 1. Given P_2 's g_0 , let the best response of P_1 be f_1 . (Note that f_1 may be the same as f_0 . Also note that, at this step of the algorithm, P_1 is allowed to change his/her strategy only in state 1). Then P_2 looks for improvements across all states, starting at state 1. Let g_1 be P_2 's best response against P_1 's f_1 . Now, P_1 tries to improve his/her payoff by changing his/her strategy in state 1. Once, P_1 makes an improvement, the ball is back in P_2 's court. If f_1 and g_1 are the best responses to each other (when P_1 is allowed a move only in state 1), P_1 moves to state 2, and so on. If no such improvements exist, then clearly we have obtained a saddle point (f^*, g^*) . The algorithm terminates, because each player has a finite number of stationary strategy pairs and no cycling occurs (that is, the above algorithm does not visit the same strategy pair (f_i, g_j) twice). For details of the proof, refer Ref. 27.

For an algorithm for a class of multi-player stochastic games, refer Ref. 45. In the next section, we present some interesting results for the advanced reader. These results assume familiarity with real analysis and measure theory, and we just outline the

results and proofs. Readers without sufficient background or readers who are not interested in these topics may skip the following section.

STOCHASTIC GAMES WITH COUNTABLE STATE SPACE AND BOREL PAYOFFS

We start off with Gale–Stewart games [46] and Blackwell games [47], and Martin’s results [48,49] on the determinacy of these games. These results can be used to prove the existence of value in TPZS stochastic games with countable state space and Borel-measurable payoff function (Maitra and Sudderth [50,51], Martin [49]).

Borel Determinacy of Gale–Stewart Games and Blackwell Games

Definition 13 [Gale–Stewart games [46]]. A Gale–Stewart game is a TPZS game of perfect information played over the infinite horizon. A_1 and A_2 are arbitrary finite, nonempty sets of actions for players P_1 and P_2 , respectively. One of the players starts the game and the game is played sequentially. P_1 and P_2 alternately choose actions from A_1 and A_2 , respectively, after observing previous actions. Without loss of generality, let P_1 be the player to move first. P_2 observes P_1 ’s action, say $i_1 \in A_1$ and chooses $j_1 \in A_2$. P_1 now observes j_1 (and already knows i_1) and chooses i_2 , and so on. Let the sequence of actions chosen be $i_1, j_1, i_2, j_2, \dots$. Let $W \subset (A_1 \times A_2)^\infty$ be the winning set for P_1 . That is, P_1 wins if $(i_1, j_1, i_2, j_2, \dots) \in W$, and P_2 wins otherwise.

Example 5. Both the players can choose either 0 or 1. That is, $A_1 = A_2 = \{0, 1\}$. Player 1 chooses 0 or 1 in the first step. Player 2 observes this move and chooses 0 or 1. Player 1 observes this and picks 0 or 1, and so on. Let the sequence of bits chosen by the players be $b_1, b_2, \dots$. The payoff to player 1 is defined as $\sum_i (b_i/2^i)$, which is a real number in $[0, 1]$. Now, given a subset $W \subseteq [0, 1]$, player 1 wins if his/her payoff is in W , and player 2 wins otherwise.

Theorem 5 [Martin [48]]. Let A_1 and A_2 be arbitrary finite, nonempty sets of actions for players P_1 and P_2 , respectively. If W is a Borel subset of $(A_1 \times A_2)^\infty$, then the zero-sum perfect-information game as defined above is determined. That is, either P_1 has a winning strategy or P_2 has a winning strategy.

In Example 5 above, if $W = [0, 1/2]$, player 1 always wins. (P_1 can always choose 0). Given $W = [1/4, 3/4]$, P_2 always wins. (If $b_1 = 1$, P_2 chooses $b_2 = 1$ so that P_1 ’s payoff $> 3/4$ and if $b_1 = 0$, P_2 chooses $b_2 = 0$ so that P_1 ’s payoff $< 1/4$).

Now, we look at Martin’s result for Blackwell games, which are TPZS games of imperfect information.

Definition 14 [Blackwell games [47]]. Blackwell defined the following class of TPZS games of imperfect information played over the infinite horizon. Let $Z = A_1 \times A_2$, where A_1 is the set of actions of player 1 and A_2 is the set of actions of player 2. In step 1, players P_1 and P_2 simultaneously pick actions i_1 and j_1 . Let $z_1 = (i_1, j_1)$. In step 2, the players simultaneously pick $z_2 = (i_2, j_2)$, and so on. Let $f : Z^\infty \rightarrow R$ be the payoff to player 1.

Theorem 6 [Martin [49]]. Blackwell games with bounded Borel-measurable payoff functions are determined.

Value of Stochastic Games with Borel-Measurable Payoffs

Maitra and Sudderth [51] discuss the existence of value in TPZS stochastic games with countable state space S , and finite sets of actions A_1 and A_2 of players P_1 and P_2 , respectively. We define transition probabilities q as defined in the section titled “Two-Person Finite Stochastic Games.”

We fix the starting state s_0 . The game, then, proceeds as follows. In step 1, the players play $i_1 \in A_1$ and $j_1 \in B_1$ and the game transitions to state s_1 , say. We denote this by $z_1 = (i_1, j_1, s_1)$. $z_1 \in Z$ where $Z = A_1 \times A_2 \times S$. Similarly, in step 2 we have $z_2 = (i_2, j_2, s_2)$. $z_1, z_2, \dots$ define the histories. The players

may play pure strategies as described above or may play mixed strategies, say σ for P_1 and τ for P_2 . (σ and τ are behavioral strategies, that is, at each stage of the game, the strategy of each player depends on the history up to that stage. In other words, $\sigma = (\sigma_1, \sigma_2, \sigma_3, \dots)$, $\tau = (\tau_1, \tau_2, \tau_3, \dots)$ where σ_1 and τ_1 are the strategies of players 1 and 2, respectively, on day 1, σ_2 and τ_2 are the strategies of players 1 and 2, respectively, on day 2, given their strategies on day 1, and so on, the strategies on the t th day depending on the history of all days up to $t - 1$).

Let $H = (A_1 \times A_2 \times S) \cdot H^\infty = (A_1 \times A_2 \times S)^\infty$ is the set of all histories. Let the payoff function f be a bounded Borel-measurable function defined on H^∞ , where the sets A , B , and S are given the discrete topology and H^∞ is given the product topology. Without loss of generality, assume $f : H^\infty \rightarrow [0, 1]$. The payoff to player 1 is the expected value of f , denoted $E_{\sigma, \tau}(f)$. We denote the resulting stochastic game by Γ_f .

Theorem 7. *The stochastic game Γ_f has a value.*

Before we discuss the outline of the proof, we note the following. Clearly, Γ_f subsumes the case of discounted and undiscounted stochastic games. We stress that only the existence of a value for Γ_f is guaranteed and not the existence of optimal strategies for both the players.

The outline of the proof is as follows. Given Γ_f , we construct an equivalent perfect-information game.

Let $v \in [0, 1]$.

P_1 chooses a function $\phi_0 : H \rightarrow [0, 1]$ such that $v_{\phi_0}(s_0) \geq v$, where $v_{\phi_0}(s_0)$ is the value of the game, where $\phi_0(i, j, s)$ is the expected payoff to player 1 when the players choose actions i_1 and j_1 , respectively, and s is the next state which is chosen with probability $q(s|s_0, i, j)$. Now P_2 chooses $h_1 = (i_1, j_1, s_1) \in H$. P_1 now chooses $\phi_1 : H \rightarrow [0, 1]$ such that $v_{\phi_1}(s_1) \geq \phi_0(h_1)$, and so on.

P_1 wins if $f(h_1, h_2, \dots) \geq \liminf_{T \uparrow \infty} [\phi_{T-1}(h_T)]$.

We denote this perfect-information game by G_v .

We can apply Martin's determinacy theorem for perfect-information games (theorem above) as the winning set of P_1 is Borel.

Let $u \in [0, 1]$, $u \leq v$. Any winning strategy for P_1 in G_v is winning for P_1 in G_u as well.

Let $v_{\sup} = \sup\{v | v \in [0, 1] \text{ such that } P_1 \text{ has a winning strategy in } G_v\}$. Then P_1 has a winning strategy for all $v \in [0, v_{\sup})$ and P_2 has a winning strategy for $(v_{\sup}, 1]$.

The value of the stochastic game Γ_f is $v_{\sup}$, and it suffices to show that the lower value is at least $v_{\sup}$ and the upper value is at most $v_{\sup}$.

Maitra and Sudderth [51] show that whenever player 1 has a winning strategy in G_v , player 1 has a strategy σ in Γ_f such that $E_{\sigma, \tau}(f) \geq v$ for all strategies τ of player 2. Further, whenever player 2 has a winning strategy in G_v , player 2 has a strategy τ such that $E_{\sigma, \tau}(f) \leq v + \epsilon$, ($\epsilon > 0$), for all strategies σ of player 1. Interested readers may refer to Ref. 51 for details of the proof.

As discussed above, Martin's theorem implies the existence of value and ϵ -optimal strategies for TPZS stochastic games with countable state space and finite sets of actions, but the existence of ϵ -equilibria is an open problem when the game is nonzero-sum.

APPLICATIONS OF STOCHASTIC GAMES

Stochastic games have been (and are being) widely applied to various fields. In this section, we briefly discuss some of these applications.

Altman [52] discusses the applications of stochastic games to queues. (Refer the section titled "Queueing Theory and Queueing Networks" in this encyclopedia for details regarding queues.) We discuss a scenario that occurs in communication networks. Given a network, the traffic assignment problem involves assigning different packets to paths in the network. BCMP (Baskett, Chandy, Muntz, Palacios) networks are a class of product-form queueing networks (refer the section titled "Product-Form Queueing Networks" in this encyclopedia) that satisfy assumptions of the traffic assignment problem. Given various nodes in the network where packets may

be queued (or various paths that the packets may take), the problem of where to queue (or which route to take) can be modeled as a stochastic game. The arriving packets are the players, and at each time instant, the state of each node (or path) may be defined by the current queue length at that node (or traffic density in that path). A player at a particular node (or path) may not know the precise congestion state of the other nodes (paths). However, given the initial state and the arrival rate, the joint distribution of the congestion state as a function of the routing policy can be computed. Refer to Ref. 52 for details.

Now, we summarize an application of stochastic games to inventory control proposed by Avsar and Gursoy [53]. In their model, there are two retailers who compete for the substitutable demand of different products. Both the retailers know the substitution rates beforehand. The demand for each product is assumed to be random, and the demand distributions are known to the retailers too. At each time instant, the retailers decide their orders depending on their current inventory levels. The payoff function of each retailer includes their corresponding revenue, holding cost, and ordering cost. The authors model this substitutable product inventory problem over the infinite horizon as a stochastic game and prove that if the ordering cost is linear, there exists a unique pair of stationary base stock strategies that constitute a Nash equilibrium. Refer to Ref. 53 for details.

Other applications of stochastic games include an application to network security by Lye and Wing [54], the traveling inspector model (Filar [55]), applications to economics (Amir [56,57]), and a more recent application to power control by Altman *et al.* [58]. Kardes [59] discusses an application of stochastic games to a homeland security decision problem. We refer the reader to the respective papers for details.

SOME RECENT WORK

Apart from some of the recent applications we discussed in the previous section, there are

some recent works on theoretical as well as computational aspects of stochastic games. For example, Brazdil *et al.* [60] show that every continuous-time stochastic game with reachability objective has a value. For solving some subclasses of such games, such as finite uniform games, they propose algorithms and discuss the complexity. Neogy *et al.* [61] discuss an algorithm to solve a mixture class of stochastic games consisting of SC and ARAT states, a class which was shown to possess the orderfield property by Sinha [62]. Krishnamurthy *et al.* [63] discuss the communication complexity of some classes of nonzero-sum stochastic games. They discuss the problem of determining the existence of pure Nash equilibria when each player knows only his or her payoffs and not that of the opponent. We refer the reader to Ref. 63 for details. Other recent works on stochastic games include the results of Ganzfried and Sandholm [64] on solving multiplayer stochastic games of imperfect information, and results of Krishnamurthy *et al.* [65] on sufficient conditions for mixtures of stochastic games to possess the orderfield property.

We also refer the reader to the additional reading list for more details on stochastic games—theoretical aspects, computational aspects, as well as applications.

MULTISTATE SYSTEM RELIABILITY

BENT NATVIG
Department of Mathematics,
University of Oslo, Oslo,
Norway

One inherent weakness of traditional reliability theory (see **Coherent Systems**) is that the system and the components are always described just as functioning or failed. The first attempts to replace this by a theory for multistate systems of multistate components were done in the late 1970s in Refs 1–3. This was followed up by independent work in Refs 4–6 giving proper definitions of a multistate monotone system (MMS) and of multistate coherent systems (MCS) and also of minimal path and cut vectors. Furthermore, in Ref. 7 upper and lower bounds for the availabilities and unavailabilities, to any level, in a fixed time interval were arrived at for MMSs based on corresponding information on the multistate components. These were assumed to be maintained and interdependent. Such bounds are of great interest when trying to predict the performance process of the system, noting that exact expressions are obtainable just for trivial systems. Hence, by the mid-1980s, the basic multistate reliability theory was established. A review of the early development in this area is given in Ref. 8. Recently, probabilistic modeling of partial monitoring of components with applications to preventive system maintenance has been extended in Ref. 9 to MMSs of multistate components.

The theory was applied in Ref. 10 to an offshore electrical power generation system for two nearby oilrigs, where the amounts of power that may possibly be supplied to the two oilrigs are considered as system states. This application is also used to illustrate the theory in Ref. 9. In Ref. 11 the theory was applied to the Norwegian offshore gas pipeline network in the North Sea, as of the end of the 1980s, transporting gas to Emden in Germany. The system state depends on the

amount of gas actually delivered, and also to some extent on the amount of gas compressed mainly by the compressor component closest to Emden. Also, rather recently, the first book [12] on multistate system reliability analysis and optimization appeared. The book also contains many examples of application of reliability assessment and optimization methods to real engineering problems. A recent review of the area is given in Ref. 13 on which the present one is based.

BASIC CONCEPTS AND BASIC BOUNDS

Let $S = \{0, 1, \dots, M\}$ be the set of states of the system; the $M + 1$ states representing successive levels of performance ranging from the perfect functioning level M down to the complete failure level 0. Furthermore, let $C = \{1, \dots, n\}$ be the set of components and S_i ($i = 1, \dots, n$) the set of states of the i th component. We claim $\{0, M\} \subseteq S_i \subseteq S$. Hence, the states 0 and M are chosen to represent the end points of a performance scale that might be used for both the system and its components. Let x_i ($i = 1, \dots, n$) denote the state or performance level of the i th component and $\mathbf{x} = (x_1, \dots, x_n)$. It is assumed that the state, ϕ , of the system is given by the structure function $\phi = \phi(\mathbf{x})$. For the following type of multistate systems, a series of results can be derived.

Definition 1. A system is an *MMS* if its structure ϕ satisfies:

- (i) $\phi(\mathbf{x})$ is nondecreasing in each argument
- (ii) $\phi(\mathbf{0}) = 0$ and $\phi(\mathbf{M}) = M$ ($\mathbf{0} = (0, \dots, 0)$, $\mathbf{M} = (M, \dots, M)$).

The first assumption roughly says that improving one of the components cannot harm the system, whereas the second says that if all components are in the complete failure (perfect functioning) state, then the system is in the complete failure (perfect functioning) state.

Figure 1. A simple network.

Table 1. States of the Simple Network System of Fig. 1

Component 2	3	0	2	3
	1	0	1	2
	0	0	0	0
		0	1	3
Component 1				

As a simple example of an MMS consider the network depicted in Fig. 1. Here, component 1 is the parallel module of the branches a_1 and b_1 and component 2 is the parallel module of the branches a_2 and b_2 . Let for $i = 1, 2$ $x_i = 0$ if no branches work, 1 if one branch works, and 3 if two branches work. The states of the system are given in Table 1.

Note, for instance, that the state 1 is critical both for each component and the system as a whole in the sense that the failing of a branch leads to the 0 state. In binary theory the functioning state comprises the states $\{1, 2, 3\}$ and hence only a rough description of the system's performance is possible. It is not hard to see that the structure function is given by

$$\phi(\mathbf{x}) = x_1 x_2 - I(x_1 x_2 = 3) - 6I(x_1 x_2 = 9),$$

where $I(\cdot)$ is the indicator function.

We now impose some further restrictions on the structure function ϕ . The following notation is needed:

$$\begin{aligned} (\cdot, \mathbf{x}) &= (x_1, \dots, x_{i-1}, \cdot, x_{i+1}, \dots, x_n), \\ S_{i,j}^0 &= S_i \cap \{0, \dots, j-1\}, \quad \text{and} \\ S_{i,j}^1 &= S_i \cap \{j, \dots, M\}. \end{aligned}$$

Definition 2. Consider an MCS with structure function ϕ satisfying

- (i) $\min_{1 \leq i \leq n} x_i \leq \phi(\mathbf{x}) \leq \max_{1 \leq i \leq n} x_i$.
If in addition $\forall i \in \{1, \dots, n\}, \forall j \in \{1, \dots, M\}, \exists (\cdot, \mathbf{x})$ such that

- (ii) $\phi(k_i, \mathbf{x}) \geq j, \phi(\ell_i, \mathbf{x}) < j, \forall k \in S_{i,j}^1, \forall \ell \in S_{i,j}^0$, we have a *multistate strongly coherent system (MSCS)*,
(iii) $\phi(k_i, \mathbf{x}) > \phi(\ell_i, \mathbf{x}) \forall k \in S_{i,j}^1, \forall \ell \in S_{i,j}^0$, we have an *MCS*,
(iv) $\phi(M_i, \mathbf{x}) > \phi(0_i, \mathbf{x})$, we have a *multistate weakly coherent system (MWCS)*.

When $M = 1$, all reduce to the established binary coherent system (BCS) (see **Coherent Systems**). The structure function $\min_{1 \leq i \leq n} x_i (\max_{1 \leq i \leq n} x_i)$ is often denoted the multistate series (parallel) structure.

Now choose $j \in \{1, \dots, M\}$ and let the states $S_{i,j}^0, (S_{i,j}^1)$ correspond to the failure (functioning) state for the i th component if a binary approach had been applied. Condition (ii) above means that for all components i and any level j , there shall exist a combination of the states of the other components, $(\cdot, \mathbf{x})$, such that if the i th component is in the binary failure (functioning) state, the system itself is in the corresponding binary failure (functioning) state. Roughly speaking, modifying [6], condition (ii) says that every level of each component is relevant to the same level of the system, condition (iii) says that every level of each component is relevant to the system, whereas condition (iv) simply says that every component is relevant to the system.

For a BCS, one can prove the following practically very useful principle: Redundancy at the component level is superior to redundancy at the system level except for a parallel system where it makes no difference. Assuming $S_i = S$ ($i = 1, \dots, n$) this is also true for an MCS, but not for an MWCS.

We now mention a special type of an MSCS. Introduce the indicators ($j = 1, \dots, M$), $I_j(x_i) = 1(0)$ if $x_i \geq j$ ($x_i < j$), and the indicator vector $\mathbf{I}_j(\mathbf{x}) = (I_j(x_1), \dots, I_j(x_n))$.

Definition 3. An MMS is said to be a *binary type multistate monotone system (BTMMS)* iff there exist binary monotone structures $\phi_j, j = 1, \dots, M$ such that its structure function ϕ satisfies $\phi(\mathbf{x}) \geq j \Leftrightarrow \phi_j(\mathbf{I}_j(\mathbf{x})) = 1$ for all $j \in \{1, \dots, M\}$ and all $\mathbf{x}$. If the binary monotone structure functions are

coherent, we have a *binary type multistate strongly coherent system (BTMSCS)*.

Choose again $j \in \{1, \dots, M\}$ and let the states $S_{i,j}^0(S_{i,j}^1)$ correspond to the failure (functioning) state for the i th component if a binary approach is applied. By the definition above, ϕ_j will, from the binary states of the components, uniquely determine the corresponding binary state of the system.

In what follows $\mathbf{y} < \mathbf{x}$ means $y_i \leq x_i$ for $i = 1, \dots, n$, and $y_i < x_i$ for some i .

Definition 4. Let ϕ be the structure function of an MMS and let $j \in \{1, \dots, M\}$. A vector $\mathbf{x}$ is said to be a *minimal path (cut) vector to level j* iff $\phi(\mathbf{x}) \geq j$ and $\phi(\mathbf{y}) < j$ for all $\mathbf{y} < \mathbf{x}$ ($\phi(\mathbf{x}) < j$ and $\phi(\mathbf{y}) \geq j$ for all $\mathbf{y} > \mathbf{x}$).

We now illustrate Definition 4 by finding the minimal path and cut vectors to all levels for the simple network system given in Fig. 1. From Table 1, it is easy to come up with the minimal path vectors and minimal cut vectors given in Tables 2 and 3, respectively. Note that the same vector may be a minimal cut vector to more than one level. This is not true for the minimal path vectors.

Definition 5. The *performance process of the i th component* ($i = 1, \dots, n$) is a stochastic process $\{X_i(t), t \in [0, \infty)\}$, where

Table 2. Minimal Path Vectors for the Simple Network System of Fig. 1

Level	Component 1	Component 2
1	1	1
2	1	3
2	3	1
3	3	3

Table 3. Minimal Cut Vectors for the Simple Network System of Fig. 1

Levels	Component 1	Component 2
1, 2	0	3
1, 2	3	0
2	1	1
3	1	3
3	3	1

for each fixed $t \in [0, \infty)$ $X_i(t)$ is a random variable which takes values in S_i . The *joint performance process for the components* $\{\mathbf{X}(t), t \in [0, \infty)\} = \{(X_1(t), \dots, X_n(t)), t \in [0, \infty)\}$ is the corresponding vector stochastic process. The *performance process of an MMS* with structure function ϕ is a stochastic process $\{\phi(\mathbf{X}(t)), t \in [0, \infty)\}$, where for each fixed $t \in [0, \infty)$, $\phi(\mathbf{X}(t))$ is a random variable which takes values in S .

Definition 6. The performance processes $\{X_i(t), t \in [0, \infty)\}$, $i = 1, \dots, n$ are *independent* in the time interval I iff, for any integer m and $\{t_1, \dots, t_m\} \subset I$ the random vectors $\{X_1(t_1), \dots, X_1(t_m)\}, \dots, \{X_n(t_1), \dots, X_n(t_m)\}$ are independent.

Definition 7. Let $j \in \{1, \dots, M\}$. The *availability*, $p_\phi^{j(I)}$ and the *unavailability*, $q_\phi^{j(I)}$ to level j in the time interval I for an MMS with structure function ϕ are given by

$$p_\phi^{j(I)} = P[\phi(\mathbf{X}(s)) \geq j \quad \forall s \in I]$$

$$q_\phi^{j(I)} = P[\phi(\mathbf{X}(s)) < j \quad \forall s \in I].$$

The corresponding *availability* and *unavailability* for the i th component to level j in the time interval I are denoted respectively by $p_i^{j(I)}$ and $q_i^{j(I)}$ for $i = 1, \dots, n$.

Note that $p_\phi^{j(I)} + q_\phi^{j(I)} \leq 1$, with equality for the case $I = [t, t]$.

As an example of the bounds for $p_\phi^{j(I)}$ and $q_\phi^{j(I)}$ given in Ref. 7, without any assumption according to Ref. 14 that each of the performance processes of the components is associated in I , we give the following theorem by first introducing the $n \times M$ matrices

$$\mathbf{P}_\phi^{(I)} = \{p_i^{j(I)}\}_{\substack{i=1,\dots,n \\ j=1,\dots,M}}$$

$$\mathbf{Q}_\phi^{(I)} = \{q_i^{j(I)}\}_{\substack{i=1,\dots,n \\ j=1,\dots,M}}.$$

Theorem 1. Let (C, ϕ) be an MMS with the marginal performance processes of its components being independent in I . Furthermore,

for $j \in \{1, \dots, M\}$ let $\mathbf{y}_k^j = (y_{1k}^j, \dots, y_{n_k}^j)$, $k = 1, \dots, n^j$ ($\mathbf{z}_k^j = (z_{1k}^j, \dots, z_{n_k}^j)$, $k = 1, \dots, m^j$) be its minimal path (cut) vectors to level j . Define

$$\ell_\phi^{j(I)}(\mathbf{P}_\phi^{(I)}) = \max_{1 \leq k \leq n^j} \prod_{i=1}^n p_i^{y_{ik}^j(I)}$$

$$\bar{\ell}_\phi^{j(I)}(\mathbf{Q}_\phi^{(I)}) = \max_{1 \leq k \leq m^j} \prod_{i=1}^n q_i^{z_{ik}^j(I)}$$

$$\ell_\phi^{**j(I)}(\mathbf{P}_\phi^{(I)}) = \prod_{k=1}^{m^j} \prod_{i=1}^n p_i^{z_{ik}^j(I)}$$

$$\bar{\ell}_\phi^{**j(I)}(\mathbf{Q}_\phi^{(I)}) = \prod_{k=1}^{n^j} \prod_{i=1}^n q_i^{y_{ik}^j(I)}$$

$$L_\phi^{*j(I)}(\mathbf{P}_\phi^{(I)}) = \max[\ell_\phi^{j(I)}(\mathbf{P}_\phi^{(I)}), \ell_\phi^{**j(I)}(\mathbf{P}_\phi^{(I)})]$$

$$\bar{L}_\phi^{*j(I)}(\mathbf{Q}_\phi^{(I)}) = \max[\bar{\ell}_\phi^{j(I)}(\mathbf{Q}_\phi^{(I)}), \bar{\ell}_\phi^{**j(I)}(\mathbf{Q}_\phi^{(I)})]$$

$$B_\phi^{*j(I)}(\mathbf{P}_\phi^{(I)}) = \max_{j \leq k \leq M} [L_\phi^{*k(I)}(\mathbf{P}_\phi^{(I)})]$$

$$\bar{B}_\phi^{*j(I)}(\mathbf{Q}_\phi^{(I)}) = \max_{1 \leq k \leq j} [\bar{L}_\phi^{*k(I)}(\mathbf{Q}_\phi^{(I)})].$$

Then

$$\begin{aligned} L_\phi^{*j(I)}(\mathbf{P}_\phi^{(I)}) &\leq B_\phi^{*j(I)}(\mathbf{P}_\phi^{(I)}) \leq p_\phi^{j(I)} \\ &\leq \inf_{t \in I} [1 - \bar{B}_\phi^{*j(I)}(\mathbf{Q}_\phi^{(I, t)})] \\ &\leq 1 - \bar{B}_\phi^{*j(I)}(\mathbf{Q}_\phi^{(I)}) \leq 1 - \bar{L}_\phi^{*j(I)}(\mathbf{Q}_\phi^{(I)}) \\ \bar{L}_\phi^{*j(I)}(\mathbf{Q}_\phi^{(I)}) &\leq \bar{B}_\phi^{*j(I)}(\mathbf{Q}_\phi^{(I)}) \\ &\leq q_\phi^{j(I)} \leq \inf_{t \in I} [1 - B_\phi^{*j(I)}(\mathbf{P}_\phi^{(I, t)})] \\ &\leq 1 - B_\phi^{*j(I)}(\mathbf{P}_\phi^{(I)}) \leq 1 - L_\phi^{*j(I)}(\mathbf{P}_\phi^{(I)}). \end{aligned}$$

Here, $\prod_{i=1}^n a_i \stackrel{\text{def}}{=} 1 - \prod_{i=1}^n (1 - a_i)$. By specializing $M = 1$ and $I = [t, t]$ the bounds reduce to the familiar ones from binary theory as given in Ref. 15. It should be admitted that the upper bounds are poor if $p_\phi^{j(I)} + q_\phi^{j(I)}$ is not close to 1.

We now apply the theory to the simple network system given in Fig. 1. We consider the time interval $I = [t_1, t_2]$ and assume that the marginal performance processes of the two components are independent in $[0, t_2]$ and also that the two branches of each component fail and are repaired/replaced

independently of each other. All branches have the same instantaneous failure rate λ and repair/replacement rate μ .

Applying Tables 2 and 3, noting that $p_i^{2(I)} = p_i^{3(I)}$, the lower bounds are given by

$$\begin{aligned} \ell_\phi^{1(I)}(\mathbf{P}_\phi^{(I)}) &= \ell_\phi^{**1(I)}(\mathbf{P}_\phi^{(I)}) = L_\phi^{*1(I)}(\mathbf{P}_\phi^{(I)}) \\ &= B_\phi^{*1(I)}(\mathbf{P}_\phi^{(I)}) = (p_i^{1(I)})^2 = p_\phi^{1(I)} \\ \ell_\phi^{2(I)}(\mathbf{P}_\phi^{(I)}) &= p_i^{1(I)} p_i^{3(I)} \leq p_i^{1(I)} p_i^{3(I)} \\ &\quad \max[1, p_i^{1(I)}(2 - p_i^{3(I)})] \\ &= L_\phi^{*2(I)}(\mathbf{P}_\phi^{(I)}) = B_\phi^{*2(I)}(\mathbf{P}_\phi^{(I)}) \leq p_\phi^{2(I)} \\ \ell_\phi^{3(I)}(\mathbf{P}_\phi^{(I)}) &= \ell_\phi^{**3(I)}(\mathbf{P}_\phi^{(I)}) = L_\phi^{*3(I)}(\mathbf{P}_\phi^{(I)}) \\ &= B_\phi^{*3(I)}(\mathbf{P}_\phi^{(I)}) = (p_i^{3(I)})^2 = p_\phi^{3(I)}. \end{aligned}$$

Noting that $q_i^{2(I)} = q_i^{3(I)}$ the upper bounds are given by

$$\begin{aligned} 1 - \bar{\ell}_\phi^{1(I)}(\mathbf{Q}_\phi^{(I)}) &= 1 - q_i^{1(I)} \geq (1 - q_i^{1(I)})^2 \\ &= 1 - \bar{L}_\phi^{*1(I)}(\mathbf{Q}_\phi^{(I)}) = 1 - \bar{B}_\phi^{*1(I)}(\mathbf{Q}_\phi^{(I)}) \\ 1 - \bar{\ell}_\phi^{2(I)}(\mathbf{Q}_\phi^{(I)}) &= 1 - \max[q_i^{1(I)}, (q_i^{3(I)})^2] \\ &\geq 1 - \max[q_i^{1(I)}, (q_i^{1(I)} + q_i^{3(I)} - q_i^{1(I)} q_i^{3(I)})^2] \\ &= 1 - \bar{L}_\phi^{*2(I)}(\mathbf{Q}_\phi^{(I)}) \geq 1 - \bar{B}_\phi^{*2(I)}(\mathbf{Q}_\phi^{(I)}) \\ &= \min[(1 - q_i^{1(I)})^2, 1 - (q_i^{1(I)} + q_i^{3(I)} - q_i^{1(I)} q_i^{3(I)})^2] \\ 1 - \bar{\ell}_\phi^{3(I)}(\mathbf{Q}_\phi^{(I)}) &= 1 - q_i^{3(I)} \geq (1 - q_i^{3(I)})^2 = 1 - \bar{L}_\phi^{*3(I)}(\mathbf{Q}_\phi^{(I)}) \\ &= 1 - \bar{B}_\phi^{*3(I)}(\mathbf{Q}_\phi^{(I)}). \end{aligned}$$

In Table 4, we give numerical values of the bounds for all combinations of $\lambda = 0.001, 0.01; \mu = 0.01$, and $I = [100, 110], [100, 200], [1000, 1100]$. The lower bounds given are representatives of the different ones listed above. Hence, for level 1, $p_\phi^{1(I)}$ is given, for level 2, $\ell_\phi^{2(I)}(\mathbf{P}_\phi^{(I)})$ and $L_\phi^{*2(I)}(\mathbf{P}_\phi^{(I)})$ are given, whereas for level 3, $p_\phi^{3(I)}$ is given. Similarly, the upper bounds given are representatives of the different ones listed above. Hence, for level 1,

Table 4. Bounds for the Availabilities of the Simple Network System of Fig. 1

	Level 1		Level 2		Level 3	
	Lower	Upper	Lower	Upper	Lower	Upper
$\lambda = 0.001$	0.9903	0.9970	0.8607	0.9886	0.7481	0.8932
$\mu = 0.01$		0.9940	0.9723	0.9880		0.7978
$I = [100, 110]$				0.9880		
$\lambda = 0.001$	0.9667	0.9995	0.7103	0.9979	0.5219	0.9543
$\mu = 0.01$		0.9990	0.8923	0.9979		0.9108
$I = [100, 200]$				0.9979		
$\lambda = 0.001$	0.9522	0.9989	0.6603	0.9954	0.4578	0.9320
$\mu = 0.01$		0.9978	0.8526	0.9952		0.8686
$I = [1000, 1100]$				0.9952		
$\lambda = 0.01$	0.5862	0.8470	0.2020	0.6012	0.0696	0.3685
$\mu = 0.01$		0.7174	0.2685	0.5268		0.1358
$I = [100, 110]$				0.5268		
$\lambda = 0.01$	0.2024	0.9747	0.0196	0.8705	0.0019	0.6401
$\mu = 0.01$		0.9500	0.0196	0.8585		0.4097
$I = [100, 200]$				0.8585		
$\lambda = 0.01$	0.1651	0.9662	0.0137	0.8349	0.0011	0.5937
$\mu = 0.01$		0.9335	0.0137	0.8182		0.3525
$I = [1000, 1100]$				0.8182		

$1 - \bar{\ell}_\phi^{1(I)}(\mathbf{Q}_\phi^{(I)})$ and $1 - \bar{L}_\phi^{*1(I)}(\mathbf{Q}_\phi^{(I)})$ are given, for level 2, $1 - \bar{\ell}_\phi^{2(I)}(\mathbf{Q}_\phi^{(I)})$, $1 - \bar{L}_\phi^{*2(I)}(\mathbf{Q}_\phi^{(I)})$, and $1 - \bar{B}_\phi^{*2(I)}(\mathbf{Q}_\phi^{(I)})$ are given, whereas for level 3, $1 - \bar{\ell}_\phi^{3(I)}(\mathbf{Q}_\phi^{(I)})$ and $1 - \bar{L}_\phi^{*3(I)}(\mathbf{Q}_\phi^{(I)})$ are given.

As we see from Table 4, the bounds for this simple network system are amazingly good. Only the upper bounds for the availability to level 2 are getting really bad; that is, for $\lambda = \mu = 0.01$ and $I = [100, 200]$, $[1000, 1100]$. In these cases, we expect more fluctuations between the states of the two components and hence of the system during I . Since our bounds are based on component availabilities and unavailabilities, a lot of information is lost in these cases, and the bounds are hence poor.

Note that we always have $1 - \bar{L}_\phi^{*2(I)}(\mathbf{Q}_\phi^{(I)}) = 1 - \bar{B}_\phi^{*2(I)}(\mathbf{Q}_\phi^{(I)})$ in Table 4. In fact, we have been unable to find values of λ , μ , and I such that this equality does not hold. For the special case $t_1 = t_2 = \infty$, it is not too hard to show this analytically.

AN OFFSHORE ELECTRICAL POWER GENERATION SYSTEM

The purpose of the offshore electrical power generation system considered in Refs 9 and

10, depicted in Fig. 2, is to supply two nearby oilrigs with electrical power. Both oilrigs have their own main generation, represented by equivalent generators A_1 and A_3 each having a capacity of 50 MW. In addition, oilrig 1 has a standby generator A_2 that is switched into the network in case of outage of A_1 or A_3 . A_2 also has a capacity of 50 MW. The control unit, U , continuously supervises the supply from each of the generators with automatic control of the switches. If, for instance, the supply from A_3 to oilrig 2 is not sufficient, whereas the supply from A_1 to oilrig 1 is sufficient, U can activate A_2 to supply oilrig 2 with electrical power through the standby subsea cables L .

The components to be considered here are A_1, A_2, A_3, U , and L . We let the perfect functioning level M equal 4 and let the set of states of all components be $\{0, 2, 4\}$. For A_1, A_2 , and A_3 these states are interpreted as

- 0: The generator cannot supply any power;
- 2: The generator can supply maximum 25 MW;
- 4: The generator can supply maximum 50 MW.

Note that as an approximation for these generators, we have chosen to describe their

Figure 2. Outline of an offshore electrical power generation system.

supply capacity on a discrete scale of three points. The supply capacity is not a measure of the actual amount of power delivered at a fixed point of time.

The control unit U has the states

- 0: U will by mistake switch off the main generators A_1 and A_3 without switching A_2 on;
- 2: U will not switch A_2 on when needed;
- 4: U is functioning perfectly.

The subsea cables L are actually assumed to be constructed as double cables transferring half of the power through each simple cable. This leads to the following states of L

- 0: No power is transferred;
- 2: 50% of the power is transferred;
- 4: 100% of the power is transferred.

Let us now for simplicity assume that the mechanism that distributes the power from A_2 to platform 1 or 2 is working perfectly, transferring excess power from A_2 to platform 2 if platform 1 is ensured a delivery corresponding to state 4. Now let $\phi(A_1, A_2, A_3, U, L)$ = the amount of power that can be supplied to platform 2. In addition to the states taken by A_1, A_2, A_3 , ϕ can also take the following states

- 1: The amount of power that can be supplied is maximum 12.5 MW;

- 3: The amount of power that can be supplied is maximum 37.5 MW.

Number the components A_1, A_2, A_3, U, L successively 1, 2, 3, 4, 5. Then a little thought leads to

$$\phi(x) = I(x_4 > 0) \min(x_3 + \max(x_1 + x_2 I(x_4 = 4) - 4, 0) x_5 / 4, 4),$$

noting that $\max(x_1 + x_2 I(x_4 = 4) - 4, 0)$ is just the excess power from A_2 which one tries to transfer to platform 2. This is, obviously, an MMS.

FORTHCOMING WORK

In a forthcoming book on multistate reliability theory with applications [16], an in depth treatment of the material presented here is given. Also, a series of new results are developed. For instance, some generalizations of bounds for the availabilities and unavailabilities, to any level, in a fixed time interval given in Ref. 7 have been established. Furthermore, the theory for Bayesian estimation of system reliability, as presented in Ref. 17 for binary systems, has been extended to multistate systems. Finally, a theory for measures of component importance in non-repairable and repairable MSCSs have been developed with accompanying advanced discrete simulation methods. This generalizes recent work given in Refs 18 and 19 for BCSs.

MULTIVARIATE ELICITATION: ASSOCIATION, COPULAE, AND GRAPHICAL MODELS

ALIREZA DANESHKHAH

Science, University of
Strathclyde, Glasgow, UK

INTRODUCTION

In the context of decision analysis, elicitation is the process of translating someone's beliefs about some uncertain quantities into a probability distribution. Elicitation is an important subject: it has an important role to play in every application where the data do not make the prior beliefs of the decision maker insignificant.

In practice, we often wish to obtain a joint distribution from the expert for two or more uncertain quantities. It is clear that even for two variables the elicitation of a joint distribution is more complex than that of the marginal distributions discussed in O'Hagan *et al.* [1] and references therein. For more than two variables, the task becomes rapidly even more complex. For instance, for three variables we need to consider probabilities such as $P(X \leq x; Y \leq y; Z \leq z)$. Unfortunately, despite the recent work, it is difficult to find research guiding us in such an elicitation. We focus on the elicitation of a single expert's beliefs about uncertain quantities. To avoid convoluted language, we let the expert be female.

The task becomes much simpler in the special case where the variables are independent. In this case, the elicitation issue would reduce to the elicitation of marginal distributions of the variables separately, and hence we do not need to think about joint distributions. However, in general, we cannot expect independence to hold in practical elicitation tasks. The uncertain variables about

which we wish to elicit judgments are all connected by arising in the same problem, and all falling in the area of expertise of the expert in question, and this is likely to imply that they are connected also in the sense that acquiring knowledge about any one variable would affect the expert's judgment about the others. There are techniques that can be used to transform a problem to make use of partial or complete independence [1–3]. However, these are practically useful only in limited circumstances—there is, therefore, substantial interest in the problem of eliciting a joint probability distribution for two or more variables. In this review, we present the approaches to elicit the models with complex dependency structures between uncertain quantities by using copulae, vines, and other relevant graphical tools.

The outline of the present article is as follows. A number of graphical models in probability theory such as a copula, vine, and Bayesian network have been developed to capture dependencies between random variables. In the section titled “Joint Distribution and Copula,” we show how a multivariate distribution can be constructed using a copula. The expert judgments required to elicit the various marginal distributions and dependence information, in the form of correlations, conditional rank correlations, and so on, are the input to these models. In the section titled “Measures of Bivariate Association,” we review the methods to elicit unconditional and conditional rank correlations. We present the minimum information algorithm as a much more flexible method defining copulae given some constraints specified by an expert, in the section titled “Expert Assessment of Minimally Informative Copula.” A vine is another way to model dependencies between uncertain quantities and can be used to build a higher dimensional distribution from two-dimensional copulae. This model, and ways to elicit conditional rank correlation required to build a joint distribution, is presented in the section titled “Elicitation Multivariate Distribution by Vines.”

JOINT DISTRIBUTION AND COPULA

The construction of a probabilistic model is a key step in many areas of analysis, including decision risk and uncertainty analysis. This can be done by constructing a joint distribution based on marginal and conditional distributions associated with the uncertain quantities. A disadvantage with this approach is that the required number of probability assessments can grow exponentially with the number of variables. The use of a copula to construct joint distributions and pairwise correlations to incorporate dependence among the variables has become very popular. The approach enables us to use an expert's subjective judgments of marginal distributions and correlations. Clemen and Reilly [4] used the copula that underlies the multivariate normal distribution, to construct a complete copula-based joint distribution using assessed rank-order correlations and marginal distributions. They reduced the number of required assessments and relaxed the need to search for conditional independence. The copula approach relies fundamentally on the ability of experts to reliably assess correlations, which may be difficult.

The essence of the copula approach is that a joint distribution, $F(x_1, \dots, x_n)$, of random variables, $X_1, \dots, X_n$, can be expressed as a function of the marginal distributions, $F_1(x_1), \dots, F_n(x_n)$:

$$F(x_1, \dots, x_n) = C(F_1(x_1), \dots, F_n(x_n)),$$

where $C(\cdot)$ is a joint distribution with uniform marginals called the *copula*. In addition to this, if each $F_i(\cdot)$ is a continuous distribution function (CDF) then $C(\cdot)$ is unique [4]. If we assume that each F_i is differentiable, we can rewrite the joint density

$$f(x_1, \dots, x_n) = f_1(x_1) \times \dots \times f_n(x_n) \times c(F_1(x_1), \dots, F_n(x_n)) \quad (1)$$

where $f_i(\cdot)$ is the density corresponding to $F_i(\cdot)$ and $c = \partial^n C / (\partial F_1 \dots \partial F_n)$, which is called the *copula density*.

Using this copula-based representation, we can break the elicitation of a joint

probability distribution into smaller, more manageable tasks: the individual marginal distributions and the copula are separately elicited. The copula is a model of the dependence between variables. There are many standard functional forms assumed for copulae.

The multivariate Gaussian copula, which is the unique copula arising from the above expression when we take any multivariate Gaussian distribution F , is a well-known and flexible copula form that can be fully specified through judgments about correlation between the variables. We present the ways to elicit multivariate Gaussian copula parameters indirectly by eliciting the conditional and unconditional rank correlations.

To understand the multivariate Gaussian copula, Clemen and Reilly [4] examine its relationship with the multivariate normal distribution that is typically parameterized in terms of Pearson product-moment correlations. Then, for each element of $\mathbf{R}^*$, the corresponding product-moment correlation r_{ij} for the multivariate normal is calculated. If $\mathbf{R}^*$ is made up of τ_{ij} (Kendall's tau) or made of ρ_{ij} (Spearman's correlation coefficient), Clemen and Reilly [4] present the formulas corresponding to the relationships between (r_{ij}, τ_{ij}) and (r_{ij}, ρ_{ij}) , respectively, as

$$r_{ij} = \sin(\pi \tau_{ij}/2) \quad r_{ij} = \sin(\pi \rho_{ij}/6). \quad (2)$$

We are now able to construct the matrix $\mathbf{R}$ with elements r_{ij} . Note that this has to be a nonnegative semidefinite matrix, and that not all choices of parameters will give such a matrix with these properties (we return to this issue later). Clemen and Reilly [4] then present a joint density based on the multivariate Gaussian copula as

$$\begin{aligned} f(x_1, \dots, x_n | \mathbf{R}^*) &= f_1(x_1) \times \dots \times f_n(x_n) \times |\mathbf{R}|^{-\frac{1}{2}} \\ &\times \exp\{-(\Phi^{-1}[F_1(x_1)], \dots, \Phi^{-1}[F_n(x_n)]) \\ &\times (\mathbf{R}^{-1} - \mathbf{I}) \times (\Phi^{-1}[F_1(x_1)], \dots, \\ &\Phi^{-1}[F_n(x_n)])^T / 2\}, \end{aligned} \quad (3)$$

where $\Phi^{-1}(\cdot)$ is the inverse cumulative distribution function of the standard Gaussian

distribution, $\mathbf{R}$ is a $n \times n$ correlation matrix in terms of r_{ij} , and $\mathbf{I}$ is the $n \times n$ identity matrix.

Clemen and Reilly [4] argued that the multivariate Gaussian copula is flexible enough for specifying joint distributions in most applications. However, if a joint distribution is constructed using a multivariate Gaussian copula, then the dependence structure between variables will preserve many of the properties of the multivariate Gaussian distribution, such as constant conditional rank correlation. As we see below, it is possible to use more general constructions to obtain a multivariate distribution.

MEASURES OF BIVARIATE ASSOCIATION

The use of the multivariate normal copula requires the assessment of correlations and marginal probabilities. The assessment of correlations would appear to be a more difficult task than assessing probabilities [1]. Although such judgments are inherently difficult, there are some approaches available to elicit measures of bivariate association. In this section, we briefly describe some approaches that can be used to elicit the copula parameters.

It is reasonable to use statistical techniques based on the expert's familiarity with statistical concepts related to correlation. For instance, an expert might be able to make a judgment regarding the percentage of variance explained, R^2 , that would result from regressing one variable on another. Another possibility is to have the expert view several scatter-plots representing different levels of correlation and select one that is consistent with the expert's belief about the strength of the relationship between the variables [5].

The second approach is called *probability of concordance*. We assess conditional or joint probabilities and relate them to the required measure of dependence. The concordance probability P_C for two independent draws (X_1, Y_1) and (X_2, Y_2) is defined as

$$\begin{aligned} P_C &= \Pr[(X_1 \leq X_2, Y_1 \leq Y_2) \text{ or} \\ &\quad (X_1 > X_2, Y_1 > Y_2)] \\ &= \Pr(X_1 \leq X_2, Y_1 \leq Y_2). \end{aligned}$$

The probability of concordance is simply related to Kendall's τ by the expression $\tau = 2P_C - 1$. This method is recommended for the situation in which a frequency or cross-sectional interpretation is reasonable [3,4].

The method, known as *conditional fractile estimates*, requires conditional estimates and uses these to derive Spearman's ρ . Given random variables X_1 and X_2 , the standard nonparametric regression representation is $E[F_1(x_1) | x_2] = \rho_{X_1 X_2} [F_2(x_2) - 0.5] + 0.5$. In this method, the analyst might have the expert make several conditional estimates and use a least-squares approach to estimate the Spearman's $\rho_{X_1 X_2}$. This method is closely related to a technique called *predictive assessment* [6,7].

One can use a combination of these methods to increase the accuracy in assessing association between two variables. Winkler and Clemen [8] studied gains in accuracy in assessing correlations by averaging different assessments from a single expert and/or from multiple experts. They asked 90 subjects to assess correlations for five pairs of variables using the following methods: strength of relationship; correlation; conditional fractile; concordance probability; joint probability; and conditional probability (see O'Hagan *et al.* [1] and Clemen *et al.* [9] for details of these methods). In the end, they conclude that asking for a correlation is simply a reasonable method, the strength of relationship is simple and also performs quite well, but the method performance based on joint probabilities was the worst in terms of both accuracy and ease of use. However, the accuracy of the better methods mentioned above is not desirable. To improve the accuracy, they propose to use multiple experts or multiple methods in terms of a promising strategy. Their analyses in terms of using averages of correlation assessments from multiple experts and/or multiple methods show a considerable increase in accuracy as they increase the number of experts or methods (see *Eliciting Subjective Probability Distributions from Groups* for details of combination of multiple experts' assessments). As a result, the variability of assessment accuracy decreases significantly

by increasing the number of experts or methods, which leads to a large risk reduction (see Clemen *et al.* [8] for details).

The *association maps* proposed by Gosling [10] are a simple visual tool for eliciting correlations used in building a copula. The basic idea behind this map is to place dots on a two-dimensional shape such that the distance between the points symbolizes the level of association. In other words, the closer the points, the higher the correlation. Although this map gives an impression of the correlation between variables, no numerical values can be obtained to help the analyst to specify the copula parameters or correlation coefficients required to construct the copula-based multivariate distribution.

EXPERT ASSESSMENT OF MINIMALLY INFORMATIVE COPULA

We introduce a methodology based on the minimum information principle that provides a much more flexible approach to defining copulae. Any quantity (or a group of quantities) depending on the two variables in question can be used through *expected values* specified by an expert. The system can give guidance on the range of values for each expected value compatible with the specifications already made by the expert. The method uses a D_1AD_2 algorithm to build the copula that minimizes the information function, given the constraints. This minimum information technique [11] is used in conjunction with expert elicitation of observables to define a copula that represents the decision makers uncertainty about the joint distribution of two random variables.

Bedford and Meeuwissen [11] applied a so-called *DAD* algorithm to produce discretized minimally informative copula with given rank correlation. The same approach can be used whenever we wish to specify the expectation of any symmetric function of U and V . In order to have asymmetric specifications we need to use the more general approach provided in Borwein *et al.* [12]. It states that if A is a positive square matrix (called a *kernel*), then we can find row vectors D_1 and D_2 such that the cell-wise product of

$D_1^T D_2$ and A is doubly stochastic. The theory also exists for continuous functions and, indeed in much more generality.

Suppose there are two random variables X and Y , with cumulative distribution functions F_X and F_Y , respectively. These are the variables of interest that we would like to associate by introducing constraints based on some knowledge about functions of these variables. Suppose there are k of these functions, namely, $h'_1(X, Y), h'_2(X, Y), \dots, h'_k(X, Y)$, and that the expert wishes to specify mean values $\alpha_1, \dots, \alpha_k$ for all these functions, respectively. We can find corresponding functions of the copula variables U and V , defined by $h_1(U, V) = h'_1(F_1^{-1}(U); F_2^{-1}(V))$, and so on, and clearly these should also have the specified expectations $\alpha_1, \dots, \alpha_k$. We form the kernel

$$A(u, v) = \exp(\lambda_1 h_1(u, v) + \dots + \lambda_k h_k(u, v)), \quad (4)$$

where u and v denote the realizations of U and V , respectively.

For practical implementations, we have to discretize the set of (u, v) values such that the whole domain of the copula is covered. This means that the kernel A described above becomes a two-dimensional matrix A and that we seek matrices D_1 and D_2 such that

$$P = D_1 A D_2 \quad (5)$$

is a doubly stochastic matrix P , that is, a discretized copula density. For each vector $(\lambda_1, \dots, \lambda_k)$, we can use the $D_1 A D_2$ algorithm to generate a unique joint density with uniform marginals. This copula gives the vector of functions $(h_1, \dots, h_k)$ an expected value vector which we call $\phi(\lambda_1, \dots, \lambda_k)$. Now, general theory [12] says that this copula is always the unique minimum information copula (with respect to the uniform distribution) giving the expected value vector $\phi(\lambda_1, \dots, \lambda_k)$. Furthermore, the mapping ϕ maps $\mathcal{R}^k$ onto the set of achievable expected value vectors. This set of possible expected value vectors is a convex set, but little else can be said about it in general. The computation details can be found in Bedford [13], Lewandowski [14], and Bedford and Daneshkhah [15].

Figure 1. A regular vine with four elements.

ELICITATION MULTIVARIATE DISTRIBUTION BY VINES

It is clear now that copulae represent a natural tool for modeling multivariate distribution. A recent generalization of copulae is that of vines [16,17] in which a multivariate distribution is built from bivariate and conditional bivariate distributions. For example, a so-called *D-vine* for four variables can be constructed with specifications of the sequence $F_1, F_2, F_3, F_4, F_{12}, F_{23}, F_{34}, F_{13|2}, F_{24|3}$, and $F_{14|2,3}$. The graph associated with this D-vine is shown in Fig. 1. Thus, graphically, a vine on n variables is a nested set of trees, where the edges of the j th tree become the nodes of the $(j+1)$ th tree for $j = 1, \dots, n-1$. A *regular vine* on n variables is a vine in which two edges in tree j are joined by an edge in tree $j+1$ only if these edges share a common node [2,16,18]. In vines, each edge in the regular vine may be associated with a conditional rank correlation. The conditional rank correlation of X and Y given Z is $r_{X,Y|Z} = r_{X_z,Y_z}$, where (X_z, Y_z) has the distribution of $(X, Y) | Z = z$.

All assignments of (conditional) rank correlations to edges of a vine are consistent, in the sense that a joint distribution exists with those correlations. This situation differs from that when directly specifying pairwise correlations as in the Gaussian copula method discussed above, as in that case there

are algebraic constraints. Any copula with an invertible conditional CDF may be used. In order to specify a joint distribution for a vine, marginal distributions and conditional rank correlations must be specified (or more generally, conditional copulae). We review a procedure for eliciting conditional rank correlations (originally presented in Morales *et al.* [19] for the Bayesian network shown in Fig. 2. This method can be easily used and generalized to other Bayesian belief networks (BBNs) and vines. To elicit $r_{4,3}$, the following question should be asked to the expert:

Q₁. Suppose that the variable X_3 was observed above its q th quantile. What is the probability that also X_4 will be observed above its q th quantile?

Figure 2. The representation of a Bayesian network with four variables.

The question requires an expert's estimate of $P_1 = P(F_4(X_4) > q \mid F_3(X_3) > q)$ (these sort of elicitation questions have been addressed in O'Hagan *et al.* [1]). The relationship between P_1 and $r_{4,3}$ depends in general on the (conditional) copula; the case of the normal and minimum information copulae is discussed above. To calculate the exceedance probability P_1 , one can numerically integrate the bivariate normal density $\phi(x_3, x_4, \rho_{4,3})$ over the region corresponding to the quantile's exceedance region $[\Phi^{-1}(q), \infty)^2$.

$$P_1 = \frac{1}{1-q} \int_{\Phi^{-1}(q)}^{\infty} \int_{\Phi^{-1}(q)}^{\infty} \phi(x_3, x_4, \rho_{4,3}) dx_3 dx_4, \quad (6)$$

where Φ^{-1} stands for the inverse standard normal CDF. Equation (2) can then be used to fit the value of the normal copula parameter ρ , given the expert estimate of P_1 .

The normal copula parameter ρ can then be found in such a way that it satisfies the expert's conditional probability statement P_1 and then be transformed into the corresponding rank correlation by using Equation (2). It was shown that the choice of copula has a strong impact on the conditional probability when $q \neq 0.5$ [19]. In addition, it was suggested to use $q = 0.5$ in combination with the normal copula (as presented above) to elicit the (conditional) rank correlation.

The following questions, Q_2 and Q_3 , should be asked to the expert in order to assess $r_{4,2|3}$ and $r_{4,1|3,2}$, in terms of the probabilities P_2 and P_3 .

- Q_2 . Suppose that not only variable X_3 but also X_2 was observed above their medians. Now, what is the probability that also X_4 will be observed above its median value?
- Q_3 . Suppose that not only variable X_3 but also X_2 and X_1 were observed above their medians. Now, what is the probability that also X_4 will be observed above its median value?

$$\begin{aligned} P_2 &= P(F_{X_4}(X_4) > 0.5 \mid F_{X_3}(X_3) > 0.5, \\ &\quad F_{X_2}(X_2) > 0.5) \\ P_3 &= P(F_{X_4}(X_4) \geq 0.5 \mid F_{X_3}(X_3) \geq 0.5, \\ &\quad F_{X_2}(X_2) \geq 0.5, F_{X_1}(X_1) \geq 0.5). \end{aligned}$$

A similar method is used to estimate P_2 and P_3 in terms of the multivariate normals [15,19].

In summary, the conditional probability technique can be considered as an aid to elicit conditional and unconditional rank correlations. The dependence relations can be revealed through the successive conditional probability assessments regarding the given nested constraints. To compute these constraints efficiently, so as to support the elicitation, the Gaussian copula is recommended by Morales *et al.* [19]. The same copula is suggested by Clemen and Reilly [4] and Gosling [10] in their studies to elicit the correlations. If the Gaussian copula is not desired then a range of other copulae, including the minimum information copulae mentioned above, can be used. However, the above elicitation procedure only specifies one parameter; so, additional questions would be needed if a copula with more parameters was to be used. For any one-parameter family of copulae, it is possible to precompute the relationship between the parameter and the probability being elicited in the question above. Hence, the analyst is not actually restricted to the Gaussian copula in practice.

MULTIVARIATE INPUT MODELING

BAHAR BILLER
Tepper School of Business,
Carnegie Mellon University,
Pittsburgh, Pennsylvania

INTRODUCTION

As large-scale discrete-event stochastic simulation turns into a tool that is used routinely for the design and analysis of service and manufacturing systems, it becomes critical to provide accurate and automated multivariate input-modeling support. Examples of multivariate inputs include the processing times of work pieces across several work centers, the product demands and the country exchange rates of global supply chains, the annual returns on stock and bond investments in portfolios, and the medical characteristics of organ-transplant donors and recipients. Multivariate input modeling helps to choose an appropriate mathematical representation of these phenomena. However, representing a multivariate input process is a challenge in today's use of simulation software packages because of the need to capture the interdependencies among the many components of the multivariate input process. If the underlying input process could be represented as a sequence of independent random variables having an identical distribution belonging to one of the standard families (e.g., beta, exponential, gamma, lognormal, normal, triangular, uniform, or Weibull), then development of an input model would be a simple task. When such simple models apply, there are a number of software packages that support automated input modeling, including ExpertFit (Averill M. Law and Associates, Inc.), the Arena Input Analyzer (Rockwell Software Inc.), Stat::Fit (Geer Mountain Software Corporation), and BestFit (Palisade Corporation). Good reviews of these models are available in Refs 1 and 2. Unfortunately, simple input models often fall short

of what is needed in a large-scale discrete-event stochastic simulation because the input processes are not inherently independent, either in time sequence or with respect to other input processes in the simulation. Furthermore, the limited shapes represented by the standard families of distributions are not flexible enough to represent most characteristics of the multivariate inputs. We can find a large number of input-modeling problems for which simple models based on independent and identically distributed random variables are inadequate, for example, interarrival times of file accesses in a computer system [3,4], medical characteristics of organ-transplant donors and recipients [5], and returns on different asset classes [6]. Therefore, it is important to develop input models that can represent multivariate input processes with a wide variety of distributional shapes and dependence structures.

A recent review of the methods of developing multivariate input models is available in Ref. 7. In this document, we review the recent advances in multivariate input modeling with focus on the development of high-dimensional input models that lead to fast sampling algorithms for driving large-scale discrete-event stochastic simulations. We specifically consider simulation input models with continuous-valued components and classify them into two types. The first type corresponds to a finite number of dependent random variables, jointly called a *random vector*. The second type captures temporal dependence that arises over a countably infinite sequence of random variables and is studied in terms of time series. More specifically, a k -variate random vector $\mathbf{X} = (X_1, X_2, \dots, X_k)'$ denotes a collection of k random components, each of which is a real-valued random variable. A k -variate time series $\{\mathbf{X}_t = (X_{1,t}, X_{2,t}, \dots, X_{k,t})'; t = 1, 2, \dots\}$, on the other hand, denotes a sequence of random vectors observed at time $t = 1, 2, \dots$. We associate with the random vector, a probability distribution function, called the *joint distribution function*, in the space $\mathcal{R}^k$.

The joint distribution completely defines the stochastic properties of $\mathbf{X}$, and hence it is often used for understanding the effect of the dependence between the components of $\mathbf{X}$ on system performance measures. On the other hand, the time series process $\{\mathbf{X}_t; t = 1, 2, \dots\}$ is a stochastic process that can be studied using the probability distribution, where it imposes on the space of all possible path realizations. Such a probability distribution completely describes the stochastic properties of $\{\mathbf{X}_t; t = 1, 2, \dots\}$. However, time series are often specified in terms of the probability distributions of the components $X_{i,t}$, $i = 1, 2, \dots, k$ and the autocorrelation structure of the sequence, that is, the sequence of correlations between the various elements of $\{X_{i,t}; i = 1, 2, \dots, k, t = 1, 2, \dots\}$. Most of our presentation in this document focuses on capturing the joint distributional properties of random vectors. However, we also provide a brief description of the extension of these models to represent stationary multivariate time series.

We discuss the multivariate input models developed for random vectors in the section titled “Input Modeling for Random Vectors” and the extension of multivariate input modeling to time series in the section titled “Input Modeling for Multivariate Time Series.” The discussion focuses on modeling high-dimensional processes via the use of flexible multivariate density models and presenting fast sampling algorithms well suited for driving large-scale discrete-event stochastic simulations. We conclude with promising areas for multivariate input-modeling research in the concluding section.

INPUT MODELING FOR RANDOM VECTORS

The multivariate normal distribution is the most frequently used distribution in multivariate input modeling. However, it possesses a number of limitations that have motivated the recent advances in multivariate input modeling. We first describe the multivariate normal distribution in the next section and then present the multivariate input models in the order of

increasing flexibility they provide to the simulation user. Specifically, we present the normal-to-anything (NORTA) distribution, the multivariate Johnson translation system, the multivariate Johnson-marginal-based distribution, and the multivariate copula-based distribution in the respective sections. It is important to note that the NORTA distribution is a special case of the multivariate copula-based distribution. The focus of the multivariate input-modeling research has been initially on the NORTA distribution, while it has recently switched to the use of copula theory for extending NORTA to capture a wide variety of dependence structures. Therefore, we discuss the development of NORTA and copula-based distributions in separate sections.

The Multivariate Normal Distribution

A k -dimensional random vector $\mathbf{X} = (X_1, X_2, \dots, X_k)'$ with mean vector $\boldsymbol{\mu}_{\mathbf{X}}$ (i.e., $(E[X_1], E[X_2], \dots, E[X_k])'$) and covariance matrix $\boldsymbol{\Sigma}_{\mathbf{X}}$ (i.e., $[\text{Cov}(X_i, X_j); i, j = 1, 2, \dots, k]$) is said to have a nonsingular multivariate normal distribution [8], in symbols $\mathbf{X} \sim \mathcal{N}_k(\boldsymbol{\mu}_{\mathbf{X}}, \boldsymbol{\Sigma}_{\mathbf{X}})$, if (i) $\boldsymbol{\Sigma}_{\mathbf{X}}$ is positive definite, and (ii) the density function of $\mathbf{X}$ is of the form

$$f(\mathbf{x}; \boldsymbol{\mu}_{\mathbf{X}}, \boldsymbol{\Sigma}_{\mathbf{X}}) = \frac{1}{(2\pi)^{k/2} |\boldsymbol{\Sigma}_{\mathbf{X}}|^{1/2}} \times \exp \left\{ -\frac{1}{2} (\mathbf{x} - \boldsymbol{\mu}_{\mathbf{X}})' \boldsymbol{\Sigma}_{\mathbf{X}}^{-1} (\mathbf{x} - \boldsymbol{\mu}_{\mathbf{X}}) \right\}.$$

We can easily generate random variates from this density function to drive stochastic simulations with multivariate normal inputs: (i) We find the Cholesky decomposition $\mathbf{P}$ of $\boldsymbol{\Sigma}_{\mathbf{X}}$. (ii) We generate k independent random variates v_i , $i = 1, 2, \dots, k$ from the standard normal distribution and construct vector $\mathbf{v} = (v_1, v_2, \dots, v_k)'$. (iii) We set $\mathbf{z} = \mathbf{P}\mathbf{v}$ and modify the components of vector $\mathbf{z} = (z_1, z_2, \dots, z_k)'$ via $x_i = \mu_i + \sigma_i z_i$ for the i th component of the multivariate input process to have mean $E[X_i]$ and standard deviation $\sqrt{\text{Cov}(X_i, X_i)}$.

However, there are two important limitations to the use of multivariate normal distribution for input modeling, especially

in large-scale stochastic simulations: (i) The marginal distribution of each component of the input model with the multivariate normal distribution is normal. (ii) Since the interactions among the components is represented in a correlation matrix, it is not possible to capture a wide variety of dependence structures. The first limitation forces the simulation user to assume unimodal, symmetric distributional shapes with a coefficient of kurtosis that is equal to three for all the components of the multivariate input model. In sections titled “NORTA Distribution,” “Multivariate Johnson Translation System,” and “Multivariate Johnson-Marginal-Based Distribution,” we present the multivariate input models that provide the simulation user the flexibility of choosing a different marginal distribution for each component of the multivariate process. The second limitation is, however, associated with the modeling of the dependencies among the components via correlations. Accounting for dependence via correlation is, in fact, a practical compromise made in multivariate input modeling. The use of correlation is often justified by the fact that making it possible for simulation users to incorporate dependence via correlation, while limited, is substantially better than the practice of ignoring dependence. However, correlation is not sufficient to describe the dependence structures that arise in situations, where extreme component realizations occur together; for example, in exchange rates that are among the input processes driving large-scale global supply chain simulations [9]. Recent research has gone beyond the use of correlation as a dependence measure and applied the copula theory that allows the consideration of dependencies between input processes in a general way and the construction of flexible density models that represent a wide variety of dependence structures. We review these copula-based multivariate distributions in the section titled “Multivariate Copula-Based Distribution.”

NORTA Distribution

A general method for obtaining random vector $\mathbf{X} = (X_1, X_2, \dots, X_k)'$ with component

marginal distributions F_{X_i} , $i = 1, 2, \dots, k$ and positive definite correlation matrix $\Sigma_{\mathbf{X}}$ specified via Pearson product-moment correlations $\rho_{\mathbf{X}}(i, j) = \text{Corr}(X_i, X_j)$, $i, j = 1, 2, \dots, k$ is the transformation-based model described in Ref. 10. The central idea behind the development of this model is to transform a standard multivariate normal vector into the desired random vector, which is referred to as having a *NORTA distribution*. Specifically, the approach is to let

$$\mathbf{X} = \left(F_{X_1}^{-1}[\Phi(Z_1)], F_{X_2}^{-1}[\Phi(Z_2)], \dots, \right. \\ \left. \times F_{X_k}^{-1}[\Phi(Z_k)] \right)',$$

where Φ is the cumulative distribution function (cdf) of the standard normal random variable and the base vector $\mathbf{Z} = (Z_1, Z_2, \dots, Z_k)'$ is a standard k -dimensional normal vector with correlation matrix $\Sigma_{\mathbf{Z}}$ composed of Pearson product-moment correlations $\rho_{\mathbf{Z}}(i, j) = \text{Corr}(Z_i, Z_j)$, $i, j = 1, 2, \dots, k$. This modeling approach works for any marginal distribution, although $F_{X_i}^{-1}$, $i = 1, 2, \dots, k$ may have to be evaluated by approximate numerical methods, when there are no exact closed-form expressions.

The challenge associated with the construction of the NORTA distribution is to find a $\Sigma_{\mathbf{Z}}$ that implies the desired correlation matrix $\Sigma_{\mathbf{X}}$ for $\mathbf{X}$. This requires the solution of a total of $k(k-1)/2$ individual correlation-matching problems of the following form, where ϑ_{ρ} corresponds to the standard bivariate normal probability density function (pdf) with correlation ρ :

$$\begin{aligned} \rho_{\mathbf{X}}(i, j) &= \text{Corr}\left(F_{X_i}^{-1}[\Phi(Z_i)], F_{X_j}^{-1}[\Phi(Z_j)]\right) \\ &= \frac{\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} F_{X_i}^{-1}[\Phi(z_i)] F_{X_j}^{-1}[\Phi(z_j)] \vartheta_{\rho_{\mathbf{Z}}(i, j)} \\ &\quad \times (z_i, z_j) dz_i dz_j - \mu_i \mu_j}{\sigma_i \sigma_j} \\ &= c_{ij}(\rho_{\mathbf{Z}}(i, j)). \end{aligned} \quad (1)$$

Solving the correlation-matching problems of this form might be a difficult task when the Pearson product-moment correlations are used. Fortunately, the corresponding

function has the properties that allows the implementation of efficient numerical search procedures to find $\rho_{\mathbf{Z}}(i, j)$ within a predetermined precision. Good references for numerical search procedures exploiting these properties are Cario and Nelson [11], Chen [12], and Biller and Nelson [13]. However, when the rank correlation (i.e., the correlation between $F_i(X_i)$ and $F_j(X_j)$) is used, solving a correlation-matching problem is an easy task because the rank correlation-matching problem reduces to $\rho_{\mathbf{X}}(i, j) = (6/\pi) \sin^{-1}[\rho_{\mathbf{Z}}(i, j)/2]$ [14].

The NORTA distribution allows the use of the standard theory for the fast generation of random vectors with given marginal distributions F_{X_i} , $i = 1, 2, \dots, k$ and correlation matrix $\Sigma_{\mathbf{X}}$: (i) We solve $k(k-1)/2$ correlation-matching problems and identify the base correlation matrix $\Sigma_{\mathbf{Z}}$. (ii) We generate realizations from a k -variate standard normal vector of the required length, say n . To obtain the sequence of independent normal vectors, $\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_n$, we first choose k independent univariate standard normal variates $v_{1,t}, v_{2,t}, \dots, v_{k,t}$ for $t = 1, 2, \dots, n$ and then multiply $\mathbf{v}_t = (v_{1,t}, v_{2,t}, \dots, v_{k,t})'$, $t = 1, 2, \dots, n$ by a $(k \times k)$ matrix $\mathbf{P}$ for which $\mathbf{P}\mathbf{P}' = \Sigma_{\mathbf{Z}}$; that is, $\mathbf{Z}_t = \mathbf{P} \mathbf{v}_t$, $t = 1, 2, \dots, n$. (iii) For $i = 1, 2, \dots, k$, we apply the transformation $X_{i,t} = F_{X_i}^{-1}[\Phi(Z_{i,t})]$, $t = 1, 2, \dots, n$ to ensure that the i th component has marginal distribution F_{X_i} .

However, the base correlation matrix $\Sigma_{\mathbf{Z}}$ identified after the solution of the correlation-matching problems might not always be positive semidefinite, violating one of the necessary conditions for a matrix to be a multivariate normal correlation matrix. This problem was postulated in Li and Hammond [15] and was proved to exist in Ghosh and Henderson [16]. Ghosh and Henderson [17] report that the failure of this transformation-based method is relatively rare in moderate dimensions and that the method fails when the correlations lie either on the boundary or in close proximity to the set of correlations achievable for the specified marginals of the process. However, they note that the problem becomes increasingly evident as the dimension of the underlying input process increases.

Considering the flexibility the NORTA distribution provides for multivariate input modeling, a natural question to ask is how to overcome the challenge of obtaining a nonpositive semidefinite base correlation matrix. A close look at the existing literature reveals several solutions to this problem. The first one is to apply the procedures proposed by Lurie and Goldberg [18] and Ghosh and Henderson [17] to find a symmetric, positive definite approximation of the base correlation matrix. The hope is that a multivariate process constructed in this manner has a correlation structure close to the desired one, because the function c_{ij} defined in Equation (1) is known to be continuous under fairly general conditions. Another solution is to use a procedure that does not need to determine the correlation matrix of the multivariate normal random vector. We provide such a procedure in the section titled “Multivariate Johnson-Marginal-Based Distribution,” while we present the solution of using a copula-vine specification for multivariate input modeling in the section titled “Multivariate Copula-Based Distribution.”

Multivariate Johnson Translation System

Here, our objective is to describe the construction of multivariate input models that are particularly easy to use and flexible enough to capture distributional characteristics such as bimodality and heavy tails. Therefore, in this section, we focus on the Johnson translation system [19] that has become one of the most popular flexible system of distributions used in simulation applications in recent years [13,20,21]. We refer the reader to Ref. 7 for other flexible families of distributions that have been given particular attention in the literature.

An input random variable X having a marginal distribution from the Johnson translation system is defined by a cdf of the form

$$F_X(x) = \Phi \left\{ \gamma + \delta g \left[\frac{x - \xi}{\lambda} \right] \right\},$$

where γ and δ are the shape parameters, ξ is a location parameter, λ is a scale parameter, and $g(\cdot)$ is one of the following transformations:

$$g(y) = \begin{cases} \log(y), & \text{for the } S_L \\ & \text{(lognormal) family,} \\ \log(y + \sqrt{y^2 + 1}), & \text{for the } S_U \\ & \text{(unbounded) family,} \\ \log\left(\frac{y}{1-y}\right), & \text{for the } S_B \\ & \text{(bounded) family,} \\ y, & \text{for the } S_N \\ & \text{(normal) family.} \end{cases} \quad (2)$$

There is a unique family, that is, choice of g , for each feasible combination of the coefficient of skewness and the coefficient of kurtosis that are not necessarily equal to zero and three, contrary to the case in the section titled “Multivariate Normal Distribution.” The range of X depends on the family of interest and within each family, a distribution is completely specified by the values of parameters ξ , λ , γ , and δ . Distributional properties of X represented by the Johnson translation system can be found in Refs 19 and 22.

The use of the NORTA distribution with components from the Johnson translation system coincides with the multivariate distribution introduced in Ref. 23 using the following k -variate normalizing translation

$$\mathbf{Z} = \boldsymbol{\gamma} + \delta_g(\boldsymbol{\lambda}^{-1}(\mathbf{X} - \boldsymbol{\xi})) \sim \mathcal{N}_k(\mathbf{0}, \boldsymbol{\Sigma}_Z). \quad (3)$$

In this representation, $\mathbf{Z} = (Z_1, Z_2, \dots, Z_k)'$ is the k -variate standard normal random vector with the $(k \times k)$ covariance matrix $\boldsymbol{\Sigma}_Z$, $\boldsymbol{\gamma} = (\gamma_1, \gamma_2, \dots, \gamma_k)'$ and $\boldsymbol{\xi} = (\xi_1, \xi_2, \dots, \xi_k)'$ are the k -variate vectors of shape and location parameters, $\boldsymbol{\delta} = \text{diag}(\delta_1, \delta_2, \dots, \delta_k)'$ and $\boldsymbol{\lambda} = \text{diag}(\lambda_1, \lambda_2, \dots, \lambda_k)'$ are the diagonal matrices, whose entries are the shape and scale parameters, and the transformation $g(\cdot)$ is defined as $g(y_1, y_2, \dots, y_k) = (g_1(y_1), g_2(y_2), \dots, g_k(y_k))$, where $g_i(y_i)$, $i = 1, 2, \dots, k$ are defined as in Equation (2). This characterization ensures that the marginal distribution of each component of the multivariate input model is a univariate Johnson distribution.

A random vector with the multivariate Johnson translation system is easy to sample using the normalizing translation defined in Equation (1) once the correlation matrix $\boldsymbol{\Sigma}_Z$ and the marginal distribution

parameters g , $\boldsymbol{\gamma}$, $\boldsymbol{\delta}$, $\boldsymbol{\lambda}$, and $\boldsymbol{\xi}$ are given. We simply use the generation procedure presented in the section titled “NORTA Distribution” for the NORTA distribution with $X_{i,t} = F_{X_i}^{-1}[\Phi(Z_{i,t})] = \xi_i + \lambda_i g_i^{-1}[(Z_{i,t} - \gamma_i)/\delta_i]$, $i = 1, 2, \dots, k$, avoiding the need to evaluate $\Phi(\cdot)$. Thus, the Johnson translation system is a particularly good choice for high-dimensional input modeling.

Multivariate Johnson-Marginal-Based Distribution

An alternative method for representing random vector $\mathbf{X}$ with mean vector $\boldsymbol{\mu}_X$ and covariance matrix $\boldsymbol{\Sigma}_X$ is to use the multivariate distribution suggested by Stanfield *et al.* [20] for multivariate input modeling. The distinguishing features of this distribution are that its construction does not require the determination of a correlation matrix for a base normal random vector and the component random variables have marginal distributions from the Johnson translation system.

More specifically, we first define a random vector $\mathbf{Y} = (Y_1, Y_2, \dots, Y_k)'$, whose components are independent standardized Johnson variates, that is, $E(Y_i) = 0$ and $\text{Var}(Y_i) = 1$ and $\text{Cov}(Y_i, Y_j) = 0$ for $i, j = 1, 2, \dots, k$. The approach of Stanfield *et al.* [20] is to let $L_X = \boldsymbol{\Sigma}_X^{1/2}$ correspond to the lower triangular Cholesky decomposition of the covariance matrix $\boldsymbol{\Sigma}_X$ and $\boldsymbol{\sigma}_X$ be a diagonal matrix whose entries are the standard deviations of the components of $\mathbf{X}$. Then, random vector $\mathbf{X} = \boldsymbol{\mu}_X + \boldsymbol{\sigma}_X L_X \mathbf{Y}$ has mean $\boldsymbol{\mu}_X$ and covariance matrix $\boldsymbol{\Sigma}_X$. Expressions that relate the skewness and kurtosis of $\mathbf{X}$ to those of $\mathbf{Y}$ are available in Ref. 20. Thus, we can start with the right parameter values for $\mathbf{Y}$ to obtain the given first four moments of $\mathbf{X}$. The computational effort needed for finding the right parameters is relatively less. Hence, it is an attractive generation method for obtaining samples with given mean vector $\boldsymbol{\mu}_X$ and covariance matrix $\boldsymbol{\Sigma}_X$ via the utilization of the relation between $\mathbf{X}$ and $\mathbf{Y}$. The resulting data-generation procedure has been shown to always match the first three marginal moments of the components and the correlation matrix of $\mathbf{X}$. However, the

approach may fail to match exactly the fourth marginal moments of the components.

Multivariate Copula-Based Distribution

Despite the recent advances in representing a wide variety of distributional shapes for the components of the multivariate input processes, the input models fall short in representing the dependence structures of simulation inputs assuming extreme realizations together. Example inputs include the returns of financial assets and the exchange rates of global supply chains. Motivated by this particular limitation of the multivariate input models, a different approach to multivariate input modeling for the last few years, has been to utilize the copula theory [24]. Specifically, a k -variate copula is a function that links together the k univariate distribution functions to form a k -variate distribution function. Sklar [25] shows that every joint distribution H_k of k components X_i , $i = 1, 2, \dots, k$ with marginal cdfs F_{X_i} , $i = 1, 2, \dots, k$ can be written as

$$H_k(x_1, x_2, \dots, x_k) = C_k(F_{X_1}(x_1), F_{X_2}(x_2), \dots, F_{X_k}(x_k)), \quad (4)$$

where C_k is a copula that is uniquely defined for continuous marginal cdfs F_{X_i} , $i = 1, 2, \dots, k$. Thus, copula C_k can be interpreted as the dependence structure of H_k .

The main advantage of using a copula for multivariate input modeling is that it remains invariant under strictly increasing transformations of the component random variables, simplifying the random vector generation. To sample a random vector $\mathbf{X} = (X_1, X_2, \dots, X_k)'$ with joint distribution H_k as defined in Equation (4), we first generate a multivariate uniform vector $\mathbf{U} = (U_1, U_2, \dots, U_k)'$ from copula C_k and then set the random vector $\mathbf{X}$ to be $(F_{X_1}^{-1}(U_1), F_{X_2}^{-1}(U_2), \dots, F_{X_k}^{-1}(U_k))'$. Thus, copulas provide an easy method to model and generate random vectors as they represent the dependence between the components of the random vector, independent of the marginal distributions.

This kind of dependence modeling is becoming increasingly popular in cases

where correlation falls short of capturing the complex interactions and interdependencies among the simulation inputs. It is important to note that the use of a normal copula for dependence modeling reduces the multivariate distribution of this section to the NORTA distribution as well as the multivariate distributions of the sections titled “Multivariate Johnson Translation System” and “Multivariate Johnson-Marginal-Based Distribution” under certain assumptions about the component marginal distributions. However, a close look at the existing literature reveals numerous parametric families of bivariate copulas that emphasize different joint distributional properties [24,26]. While these parametric families can be coupled with arbitrary marginal distributions to form bivariate input processes with a wide variety of dependence structures, the selection of a multivariate copula appropriate for multivariate input modeling is a challenging problem, limited by the small number of copula parameters that are not sufficient for representing all of the interactions among the components of the multivariate input process.

However, the multivariate copula resulting from the application of the copula-vine specification overcomes this challenge, providing the simulation user full flexibility not only in achieving a wide variety of distributional shapes for the components, but also in admitting various dependence structures among the components. The copula-vine specification introduced by Cooke and his coauthors [27–30] are described in detail in Ref. 31. Specifically, a vine associated with a k -variate random vector is a nested set of $k - 2$ spanning trees where the edges of tree j are the nodes of tree $j + 1$, starting with a tree on a graph with the k components as nodes. A regular vine on the k components is a vine in which two edges in tree j are joined by an edge in $j + 1$ only if they share a common node in the j th tree for $j = 1, 2, \dots, k - 2$. Thus, there are a total of $k(k - 1)/2$ edges in a regular vine and the representation of each edge with a different distribution leads to the construction of a k -variate distribution.

Cooke [27] provides a generation procedure that is easy to implement for the fast

sampling of a random vector from the regular vine. Sampling starts with k independent uniform samples and proceeds by traversing the vine in a specific order and applying successive inversions of the conditional distributions derived from the bivariate copulas of each edge [7]. The joint distribution of the random vector generated by this procedure is unique. Cooke [27] demonstrates how to implement this procedure by associating minimum information copulas with the vine edges, while Bedford and Cooke [29] associate elliptical copulas with the edges of the vine. The use of elliptical copulas has the advantage that the conditional correlations of the edges are related by a set of recursive equations, to the set of correlations induced between the components of the random vector generated by the vine-traversing procedure. Therefore, a set of conditional rank correlations of a regular vine can be derived for any desired correlation matrix and the method can be used for matching a given $k \times k$ rank correlation matrix to uniform marginals. Additionally, conditional distributions of elliptical copulas can be derived in explicit form and are very easy to invert. Thus, the generation procedure involves applying $k(k-1)/2$ of these inverses to k independent uniform variates, and it is fast and efficient. This procedure can match any feasible correlation matrix with uniform marginals in the trivariate case [30]. The method also comes very close to achieving any feasible correlation matrix in higher dimensions. And recently, Biller [32] has associated Archimedean copulas, which have the ability to capture different levels of (tail) dependencies in the lower-quadrant tail and upper-quadrant tail of the joint distribution, with the edges of the vine. This leads to the development of a fast sampling algorithm for multivariate input processes whose dependence structures exhibit positive tail dependencies.

INPUT MODELING FOR MULTIVARIATE TIME SERIES

Much of the previous work on multivariate time series input modeling is based on univariate and bivariate time series models.

A detailed review of these models can be found in Ref. 7. In this document, the focus is on the representation of high-dimensional time series input processes via the use of flexible multivariate density models that work for a wide variety of distributional properties and dependence structures. Such comprehensive support for multivariate time series input modeling comes from the vector-autoregressive-to-anything (VARTA) input model developed for k -variate p th-order stationary time series [13]. This model is superior to prior stochastic input models because of its ability to characterize dependencies both in time sequence and with respect to other input processes in the simulation. It also represents the key features of the components through the Johnson translation system.

Specifically, the p th-order VARTA process defines a stationary, k -variate time series $\{X_{i,t}; t = 0, 1, 2, \dots\}$, $i = 1, 2, \dots, k$ with marginal cdfs F_{X_i} , $i = 1, 2, \dots, k$ and product-moment correlations $\rho_{\mathbf{X}}(i, j, h) = \text{Corr}(X_{i,t}, X_{j,t-h})$, $h = 0, 1, 2, \dots, p$, $i, j = 1, 2, \dots, k$. It is defined by an inverse transformation from a standardized normal vector autoregressive process $\{\mathbf{Z}_t = (Z_{1,t}, Z_{2,t}, \dots, Z_{k,t})'; t = 0, 1, 2, \dots\}$ of order p with representation $\mathbf{Z}_t = \sum_{h=1}^p \alpha_h \mathbf{Z}_{t-h} + \mathbf{Y}_t$, $t = 0, 1, 2, \dots$, where α_h , $h = 1, 2, \dots, p$ are k -variate autoregressive coefficient matrices and $\{\mathbf{Y}_t = (Y_{1,t}, Y_{2,t}, \dots, Y_{k,t})'; t = 0, 1, 2, \dots\}$ is a sequence of independent and identically distributed k -variate normal random vectors, each of which has a zero mean vector and a k -variate covariance matrix denoted by $\Sigma_{\mathbf{Y}}$. The selection of $\Sigma_{\mathbf{Y}}$ as $\Sigma_{\mathbf{Z}}(0) - \sum_{h=1}^p \alpha_h \Sigma'_{\mathbf{Z}}(h)$, where $\Sigma_{\mathbf{Z}}(h)$ is the lag- h autocorrelation matrix, insures the standard normality of the base component time series $\{Z_{i,t}; t = 0, 1, 2, \dots\}$, $i = 1, 2, \dots, k$.

The major challenge in the construction of the VARTA process is to select the base correlations $\rho_{\mathbf{Z}}(i, j, h)$, $i, j = 1, 2, \dots, k$, $h = 0, 1, 2, \dots, p$ that gives the prespecified input correlations $\rho_{\mathbf{X}}(i, j, h)$, $i, j = 1, 2, \dots, k$, $h = 0, 1, 2, \dots, p$ by solving $pk^2 + k(k-1)/2$ correlation-matching problems of the form in Equation (1) with X_i replaced by $X_{i,t}$ and X_j replaced by $X_{j,t-h}$. Notice that the VARTA distribution reduces to the NORTA distribution

for $p = 0$. Therefore, the numerical search procedures of the section titled “NORTA Distribution” can also be used for solving the correlation-matching problems of the VARTA distribution. Furthermore, we can easily generate multivariate time series of length n with component marginal distributions F_{X_i} , $i = 1, 2, \dots, k$ and input autocorrelation matrices $\Sigma_{\mathbf{X}}(h) = [\rho_{\mathbf{X}}(i, j, h); i, j = 1, 2, \dots, k, h = 0, 1, 2, \dots, p]$: (i) We solve the correlation-matching problem for the base autocorrelation matrix $\Sigma_{\mathbf{Z}}(h)$ that would match the prespecified input autocorrelation matrix $\Sigma_{\mathbf{X}}(h)$ for $h = 0, 1, 2, \dots, p$. (ii) We obtain base process parameters $\alpha_1, \alpha_2, \dots, \alpha_p$ from $\Sigma_{\mathbf{Z}}(h)$, $h = 0, 1, 2, \dots, p$ by using the multivariate Yule–Walker equations [33]. Then, we compute covariance matrix $\Sigma_{\mathbf{Y}}$ as equivalent to $\Sigma_{\mathbf{Z}}(0) - \sum_{h=1}^p \alpha_h \Sigma_{\mathbf{Z}}'(h)$. (iii) We obtain starting values for $\mathbf{z}_{-p+1}, \mathbf{z}_{-p+2}, \dots, \mathbf{z}_0$ using $\Sigma_{\mathbf{Z}}(h)$, $h = 0, 1, \dots, p$. Additionally, we generate a series of normal vectors $\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_n$ using $\Sigma_{\mathbf{Y}}$, so that, we can generate time series $\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_n$ recursively from $\mathbf{z}_t = \sum_{h=1}^p \alpha_h \mathbf{z}_{t-h} + \mathbf{y}_t$ for $t = 1, 2, \dots, n$. (iv) Finally, we transform the generated base time series $\{z_{i,t}; i = 1, 2, \dots, k, t = 1, 2, \dots, n\}$ with standard normal marginal distributions into the desired process $\{x_{i,t}; i = 1, 2, \dots, k, t = 1, 2, \dots, n\}$ with cdfs F_{X_i} , $i = 1, 2, \dots, k$ by implementing the inverse transformation $x_{i,t} = F_{X_i}^{-1}[\Phi(z_{i,t})]$ for $i = 1, 2, \dots, k$ and $t = 1, 2, \dots, n$.

However, after solving the correlation-matching problems, the resulting base autocorrelation matrix might not be positive definite and/or the resulting autoregressive coefficients might violate the stability condition, that is, the roots of the reverse characteristics polynomial $|\mathbf{I}_{k \times k} - \alpha_1 \mathbf{z} - \alpha_2 \mathbf{z}^2 - \dots - \alpha_p \mathbf{z}^p| = 0$ might not lie outside of the unit circle in the complex plane ($\mathbf{I}_{k \times k}$ is the $k \times k$ identity matrix), and/or the resulting covariance matrix $\Sigma_{\mathbf{Y}}$ might not be positive definite. Therefore, there exist sets of marginals with feasible input autocorrelation structures that are not representable by the VARTA transformation. However, the copula-based multivariate time series input model of Biller [32] includes the VARTA model as a special case and works for sets of marginals with feasible

autocorrelation structures that are not representable by the VARTA transformation.

CONCLUSION

Since simulation inputs form the core of every stochastic simulation, it is important to develop multivariate input models that lead to improved system representations for accurate results and better decisions. Research on multivariate input modeling for stochastic simulations is far from being complete. There are many interesting problems that promise both methodological and practical impacts.

Most of the multivariate input-modeling research focuses on the representation of stationary input processes. However, the joint distributional properties of multivariate time series processes often vary with time. Therefore, it is critical to develop multivariate input models that represent multivariate time series input processes with possibly many components having time-varying distributional properties. It is also important that the resulting models apply to a wide variety of dependence structures and lead to the development of fast sampling algorithms for the input models to drive large-scale discrete-event stochastic simulations.

The presentation in this document has focused on the modeling and variate-generation aspect of the multivariate input modeling. Another important aspect of input modeling is to fit models to historical data. A close look at the existing literature indicates a lack of statistically valid fitting algorithms well suited for large-scale discrete-event stochastic simulations. Development of algorithms that produces estimates with good statistical properties is a promising area of research.

INTRODUCTION

Music listening and music making are important human experiences that enrich our lives and stimulate our brains. Advances in modeling and computing technologies are opening doors to new ways to create and understand music. Devices for interacting with music, ranging from mobile phones to video games, pervade our lives. The need for efficient ways to represent, organize, manipulate, and access digital music media has never been greater. In response to this growing need, the number of researchers and quantity of publications in music information research has grown exponentially over the past decade. Some recently founded conferences and societies are listed in Ref. 1. Operations research (OR) has much to offer the music research community; modeling techniques such as dynamic programming (DP), network optimization, and linear and nonlinear programming are already employed in music research. Much more can be done and improved. It is our goal to survey some advances at the intersection of music and OR, as a starting point for the reader to delve further into this exciting new field.

Music, broadly considered to be organized sound, lends itself readily to numeric representation. Sound is produced by vibrations, often at quantifiable frequencies. When these frequencies exist, they give rise to pitched sound. A sound with a perceived pitch is called a tone. A tone of a given duration can

be represented by a note. Like many human experiences, music exists in time, and unfolds over time. A sequence of notes form a melody, which is a single musical voice; the sequence of note durations gives the rhythm of the melody. A complete musical composition can be regarded as a layered collection of musical voices. Vertical collections of synchronous sounds form chords or harmonies; a sequence of harmonies forms a chord progression.

The human brain, when exposed to music, learns to perceive more abstract musical structures such as key and meter. A musical sequence often generates the perception of key and meter, unless a composer explicitly avoids these constructs. Key refers to the pitch set used in a composition; it also establishes a hierarchy of perceived stability amongst the pitches. Articulation of the most stable of these pitches gives rise to a sense of musical closure, either of a phrase or larger section of a piece. Meter refers to the time structure of the music, with strong and weak beats occurring over an underlying grid of regular pulses. Meter, amongst other things, is how we can tell the difference between a waltz and a tango. Abstract structures such as key and meter also evolve over time, and can themselves be modeled as sequences.

Creating new music, whether by improvisation or composition, can be considered the mapping of a sequence of decisions over a space of possible choices, constrained by aesthetics, common practice, or arbitrary rules. A performance, too, can be considered the result of a series of decisions on variables such as fingering, loudness, timbre, and deviations from the prescribed rhythm, constrained somewhat but not entirely by the composer's markings in the score, and the musical structure.

With the above prelude, it should not come as a surprise that music analysis, music perception and cognition, music composition and improvisation, and expressive performance, can be modeled mathematically and computationally as optimization problems. With the proliferation of and

widespread access to digital music, automatic ways to quantify and describe musical properties have become indispensable tools for managing enormous amounts of digital music.

The gamut of OR techniques that have been applied to music information research range from the traditional optimization areas of linear and nonlinear programming, DP, combinatorial optimization, network flows, and Markov models, to machine learning and hidden Markov models (HMMs). The first part of this article gives a brief overview of a range of mathematical problems and models employed in music. The sequential nature of music makes it particularly amenable to DP models. The second part of this article delves into the use of DP across a number of musical applications.

MUSIC REPRESENTATION

Mathematical and computational models of musical problems must first begin with a mathematical representation of music. Music information researchers categorize music representations into *symbolic* and *audio* data. Symbolic representations describe music through possibly layered or synchronous note sequences, represented in terms of discrete note attributes such as pitch, position, and duration. Examples of symbolic representations include text-based human-readable formats such as ***kern* (*kern.humdrum.net*), *MuseData* (*www.musedata.org*), *Guido* (*www.informatik.tu-darmstadt.de/AFS/GUIDO*), and *Music XML* (*www.recordare.com/xml.html*), as well as the more free-form musical instrument digital interface (MIDI) format which contains event-based information such as pitch number, onset time, onset velocity, and offset time. Guido, MusicXML and other representations are reviewed in Ref. 2. Symbolic information has the advantage of being discrete, thus accurately representing our abstract understanding of pitch, onset position, and note length.

Audio data refers to music sound files. Analysis of audio information is typically preceded by a spectral decomposition of the

signal. Researchers who start from the audio music signal often tackle problems similar to those who work from symbolic information, with the exception that audio signals present the added challenge of recovering the notes, chords, rhythms, or other discrete musical attributes. The mapping of audio to symbolic information (such as the score) is itself an interesting optimization problem that will be discussed in the latter half of this article.

Pitches, Chords, and Keys

Apart from straightforward numerical quantification of a musical property, representations can be designed to abstract patterns from the basic numeric quantities, or to model perceived relations between the entities. For instance, a straightforward pitch representation, such as MIDI, labels each pitch activated by a lever on a piano keyboard with a single number. Pitches can be grouped into equivalence classes using modulo 12 arithmetic so that all pitches whose frequencies are related by factors of 2^n , where $n \in \mathbb{Z}$, are grouped under the same class (i.e., all the different notes related by an octave). Numerous articles exist that explore the group theoretic properties of these pitch and interval classes [3–5].

The neo-Riemannian framework [6,7] employed by music theorists to chart chord progressions, consists of a network of pitches in two dimensional space—the *tonnetz* (tone network)—in which cliques are triads (three-note chords), and neighboring triads share two common pitches. Recent work by Callender *et al.* generalizes this space to all possible chords in non-Euclidean space [8,9].

Music psychologists have proposed spatial representations of pitches that reflect their perceived relations, for example Ref. 10. A historical review can be found in Ref. 11. Krumhansl's pitch, chord, and key maps [12] are obtained by applying multidimensional scaling to experimental data. The experimentally obtained pitch profiles serve as prototype templates for key finding. DP approaches to key finding will be discussed in the latter part of this article. Toiviainen [13] uses self-organizing maps to track and visualize the evolution of key in Krumhansl's key space.

Cognitive scientists Longuet-Higgins and Steedman independently discovered the harmonic network, equivalent to the *tonnetz*, and used it to automate the task of key finding [14]. Inspired by this work and von Neumann's interior point method, [15], Chew used the interior of the three-dimensional configuration of the harmonic network to represent pitches, chords, and keys. The calibration of this "spiral array" is a nonlinear constraint satisfaction problem. The model is used to build more robust key finding algorithms [16,17]. Chew and François use an exponentially decaying function to track long-term (key) and short-term (chord) tonal contexts in the spiral array, in their interactive tonal visualization system, MuSA.RT [18].

In the related realm of convex optimization, Kassakian and Wessel [19] propose a solution method for computing positions in Euclidean space for new musical entities, citing examples for key and melody. Suppose we have a set of data points in Euclidean space, where distance corresponds to dissimilarity. Given a new data point and dissimilarity measures to the existing points, the nonconvex problem is one of finding a position for the new point such that it minimizes the sum of squared errors between desired dissimilarities and achieved distances. The problem's dual with Lagrangian relaxation is convex, and the dual of the dual, also convex, is solved using semidefinite programming.

Melodies

We now consider mathematical models for note sequences. A sequence of notes forms a melody. Melodies can be segmented into phrases, and both melodies and phrases can contain identifiable repeating patterns called motifs. The prototypical example of a motif is the opening four notes of Beethoven's Fifth Symphony. The motif repeats throughout the composition, both locally and globally, in some combination of the following guises: verbatim, transposed, or inverted. Because melodies behave very much like sequences of text, any model for representing, indexing, analyzing, comparing, and generating text strings, such as Markov models, suffix trees, and edit distance, can also be applied to

melodic sequences. The fundamental building blocks of these models tend to be the basic units of pitch numbers or intervals, and durations or duration ratios.

Melody analysis algorithms often cannot be easily dissociated from the representation. Buteau has proposed topological spaces for motivic analysis [20], and Lartillot network-based representations for pattern extraction [21]. Combinatorial explosion remains a challenge for these techniques. Conklin and Anagnostopoulou propose a viewpoints method for discovering recurrent patterns in segmented melodies [22]. Inspired by linguistics models, Lerdahl and Jackendoff use tree structures to model the perceptual groupings of not only pitches, but also rhythm and meter [23]. Rens Bod analyzes melodic phrase structure with the linguistically oriented probabilistic context-free grammars [24]. Other generative models are covered in later sections on composition and improvisation.

Rhythm and Meter

At the most basic level, the time structure of a note can be represented as an onset with some duration. Musical rhythm can be indicated with a sequence of numbers representing onsets or durations. It can also be represented as a sequence of duration ratios. Toussaint [25] uses geometric shapes inscribed in a circle to represent musical rhythms, similar to the approach taken by Schell [26] to represent chords.

Durations or onset sequences give rise to beats (regular pulses) and meter (periodic groupings and accent patterns that persist over time). For example, marches tend to be in duple meters, typically having four beats in a measure or bar, with accents on the first and third beats, the first being stronger than the third, and waltzes in triple meter, having three beats to a measure. The rate of beats is called tempo, and is a parameter that is manipulated in expressive performance, which will be addressed in a later section.

In Lerdahl and Jackendoff [23], we have an example of a model for musical rhythm and meter that parses adjacent notes and builds a tree structure. Other models, such as Volk's inner metric analysis [27] and Smith

and Honing's wavelets approach [28] consider events over multiple time scales to uncover hierarchical metric patterns.

COMPOSITION AND IMPROVISATION

Composition can be expressed in terms of decision variables, constraints, and objective functions. This section surveys some mathematical models for musical problems in composition.

Chord Progressions: A Shortest Path Problem

A typical task in composition is the assignment of chords to harmonize a melody. A rudimentary criterion of a successful composition is that transitions between chords must be smooth; that is, the interval between successive notes in a "voice" should be as small as possible. This is sometimes referred to as parsimonious voice leading.

Consider the problem of assigning accompanying chords to the notes of a melody. For each of the N notes in the melody, one can enumerate all plausible accompanying chords. Each chord is represented by a node while an arc connects each node at time n (coincident with the n th note) with each node at time $n + 1$. A cost is now associated with each arc that reflects the distance between the adjacent chords in terms of voice leading. The problem of determining the accompanying chords with smooth voice leading becomes one of minimizing the total cost of the arcs traversed from time 1 through N . Linear programming or DP are both valid solution methods for this shortest path problem. We shall elaborate on DP as a solution technique across multiple musical problems in the latter part of this article.

Distance minimization, as the only criterion, can lead to trivial or uninteresting solutions. Constraints offer an effective way to capture more aspects of creative composition. For example, using constraints, we could require that the melody note be a member of the chord accompanying it, or that accompanying one of its neighbors (to model what are called passing tones and suspensions); or, we could have a model that prescribes accompanying chords, but not their inversions.

Constraints in Computer-Assisted Composition

Constraints present a natural way to model the composition process. Sometimes the constraints or rules are decided by common practice, sometimes by the desired auditory effect, and sometimes they are arbitrarily created by a composer to help define and shape the composition. To quote from Stravinsky [29, p. 152],

"My freedom consists in my moving about within the narrow frame that I have assigned myself for each one of my undertakings. . . . The more constraints one imposes, the more one frees one's self of the chains that shackle the spirit."

The numbers and types of musical constraints are limited only by one's imagination. In the preceding section, we mentioned some examples of constraints in harmonizing a melody. A survey of constraint-based models for harmonization can be found in Ref. 30. Truchet and Codognet present a catalog of fourteen constraint satisfaction problems in computer-assisted composition that are solved using adaptive search [31]. Some of these problems are described below.

Network Problems in Composition

Apart from minimizing voice leading distance in chord transitions, sometimes composers wish to constrain chord progressions in ways to achieve a slightly different auditory effect.

The following two examples are given in Ref. 31. A composer may wish to find an ordering of a sequence of chords so that any two consecutive chords have a fixed number of common tones, or some maximum or minimum number of common tones. The appropriate network can be constructed with the chords as nodes, and having an arc between any two nodes that satisfy the common tones criterion or criteria. The problem then becomes one of finding a Hamiltonian path through the graph, which can be solved using the traveling salesman problem algorithms.

Another composer may wish to find an ordering that maximizes the number of common tones between adjacent chords. Again, let the chords be nodes, and the arc between

each pair of nodes having a cost reflecting the number of common tones between the chords. The problem becomes a traveling salesman problem when one negates the costs.

In 2004, composer Tom Johnson (personal communication) posed the following problem to his mathematician friends: for all six-note chords from a nine-note scale, find the largest set of chords that have m tones in common with each other. Suppose that each chord is a node, and an arc connects each pair of chords having m common tones. The problem can be re-framed as one of finding the maximal clique in this graph. More mathematical puzzles for composition, and their musical solutions can be found at www.editions75.com.

Constraints on Melody and Rhythm

The fugue subjects in Bach's *48 Preludes and Fugues* are perfect examples of melodies that satisfy stringent compositional constraints. The fugue subjects are designed so that some combination of multiple instances of the subject, either in its original form, transposed (played higher or lower), inverted, reversed (in retrograde), augmented (stretched out in time), or diminished (squished in time), whether simultaneously or staggered, sound harmonious together.

Some compositional techniques, such as *serialism*, seek musical sequences that explicitly avoid repetition. A recent example of such a problem arises in Ref. 31 as follows: find permutations of the numbers $\{1, \dots, n\}$ such that the difference between consecutive numbers is never repeated, that is no interval is repeated in the sequence.

Examples of constraints one could impose on rhythm include the following: finding parallel streams of duration patterns so that no two notes entering simultaneously have the same durations; or, creating streams of durations consisting of pairs of consecutive numbers in the Fibonacci sequence such that the sum of durations in each stream is a constant.

Generating Music: Markov Models

There is a long history of composers using formal mathematical methods to generate music. The methods employed include

probability (such as in Mozart's dice game), stochastic processes, game theory [32,33], and chaos theory [34]. Markov models are the traditional generators of choice for emulating style [35,36], while a newer model uses a data structure called a factor oracle to learn patterns from musical sequences [37].

Markov chains have formed the backbone of a number of music generation systems. The states can be any combination of musical entities, such as pitches, chords, durations, pitches with durations (notes), and so on. Consider the concrete example of learning from a sample melody. For each note, one can calculate the probability that it is followed by any other note to create a first-order Markov chain. Generalizing from this concept, one could construct an n th order Markov model, where $n > 1$, from any music data stream.

Markov models are particularly suited to generating music in a given style, as captured by the transition probabilities. They have been used to analyze and generate Palestrina style counterpoint [38], and to produce style-specific accompaniment [36]. Markov models, of fixed or variable order, have also been used in human-machine improvisation systems to generate music in the style of some user-provided musical input [35,37]. The systems build Markov models from the input, then generate more music by traversing the graph according to the assigned probabilities.

MUSIC ANALYSIS

Music analysis is the process of breaking music down into smaller parts, such as chords and keys or melody streams, so as to better understand its content. Computational music analysis involves the automatic extraction of music structures such as those described in the section on music representations. The analysis of basic musical structures serves as a prelude to the understanding of more complex musical forms and gestures, some of which will be addressed in the section on expressive performance.

For every structure that exists, the automatic recognition of that structure—such as chord recognition, key finding, rhythm estimation, and meter induction—forms a

computational problem of interest. The representation of a music structure is often closely linked to algorithms for recognizing it. Consequently, as we introduced each music representation earlier, we also touched upon algorithms for automatic assignment of corresponding labels.

Pitch Structure Analysis: Keys, Chords, and Melodies

Key induction is the problem of determining the key of a music stream. We briefly mentioned some algorithms for key induction [12, 14, 16] in the section titled “Pitches, Chords, and Keys.” Other solution methods, including Refs 12 and 39 are reviewed in the section titled “Pitch Structure: Key and Chord Analysis.” The problems of segmenting a musical piece into regions of the same key and chord labeling will also be discussed in the section on pitch structure.

Moving from vertical (synchronous) to horizontal (sequential) pitch structures, the next paragraphs will review analysis methods for melodies.

An important problem in music information retrieval is the computing of music similarity, an example for which is melodic similarity. A typical solution to this problem is the computing of the edit distance, which can be solved using DP. In Ref. 40, Typke *et al.* propose the use of the Earth Mover’s Distance (EMD) to measure melodic similarity. The calculation of the EMD can be formulated as a linear programming problem, which can be solved using the simplex method. This EMD method extends to polyphonic music.

Another interesting problem in the analysis of note streams is that of voice separation, sometimes known as *stream segregation*. In the symbolic domain, voice separation takes music having multiple stream layers and separates them into their component voices in accordance to some subset of the principles of auditory streaming [41], such as voices tend not to cross, and voices tend to move by stepwise motion. Optimization-related algorithms for voice separation include Temperley’s rule-based approach using DP [42], Kilian and Hoos’ local search

[43], and Chew and Wu’s contig mapping algorithm [44].

Sequence alignment problems will be addressed in the section titled “Score Alignment.”

Time Structure Analysis: Meter, Tempo, and Rhythm

Given a rhythm, a sequence of onset times or of durations, algorithms for determining the periodicity and accent patterns of musical beats, that is meter induction, include Refs 27 and 28, mentioned in the section titled Rhythm and Meter. In Ref. 45, Klapuri *et al.* use an HMM for the tatum (a term coined by Bilmes [46], referring to the smallest unit of musical time needed to represent all events as multiples of that unit), beat, and measure. Rhythm estimation will be addressed in the section titled “Time Structure: Rhythm Estimation.”

In expressive performance, tempo (and loudness) variation can be used to indicate, and guide the perception of, groupings. Musical expression is also designed to communicate and elicit emotions from the listener. For example, a fast tempo engenders excitement; music perceived to be sad is typically slow. Thus, a problem of interest to the analysis of expressive performance, is that of beat and tempo (beat rate) tracking. A number of algorithms have been proposed for beat and tempo extraction. For example, Dixon [47] uses multiple hypothesis search while Goto [48] uses autocorrelation and cross-correlation to determine tempo. Reference 47 also provides a broad review of the literature.

Using a tempo-loudness space, Goebel *et al.* [49] employ self-organizing maps to analyze expressive gestures. Widmer and Tobudic apply machine learning to learn tempo and dynamic (loudness) strategies at different timescales [50]. Because tempo and/or dynamics vary to indicate phrase groupings [51], a performer’s phrasing strategies can be directly inferred from tempo and dynamic data. Chuan and Chew [52] use DP to automatically extract phrases from tempo time series, and Cheng and Chew [53] propose quantitative measures for evaluating phrasing strategies.

DYNAMIC PROGRAMMING

Given the sequential nature of so many aspects of music, it is not surprising that DP has many musical applications. In essentially all of these applications, the musical sequences are viewed as paths through a state graph, in which costs (or scores) are assigned to the arcs in the graph. In such a case, it is well known that DP can be used to find the least costly (or best scoring) path through the graph with computation proportional to the number of arcs in the graph.

It is important to understand the fundamental limitation on the types of objective functions that can be optimized with DP: as the cost of a path is expressed as the sum of arc costs traversed, the objective function is composed as a sum of terms depending on the values of adjacent pairs of sequence elements. That is, DP can optimize functions depending on *local* characteristics of the sequence, but not *global* ones. Fortunately, there are a great number of musical problems whose objectives fit naturally into this paradigm.

Fingering Problems

Piano fingering offers a simple yet interesting example of a musical DP problem. Suppose we are given a sequence of musical notes which are to be played by the right hand of the pianist. To each of the notes we will assign a finger, $\{1, \dots, 5\}$, with 1 representing the thumb, 2 the index finger, and so on. Thus, each possible sequence with elements in $\{1, \dots, 5\}$ constitutes a fingering of the passage.

The plausibility of each possible fingering can be captured by assigning penalties to each pair of adjacent fingering assignments. Simply by playing two notes at the same time with different finger pair combinations, we see that some are more natural than others, due to stretches involved, the unique role of the thumb, as well as other considerations. Thus, one can assign a cost to each fingering of each pair of neighboring notes, and optimize the sum of costs using DP.

This DP technique was first proposed by Parncutt [54], and later extended by Jacobs [55]. An *“in vivo”* view of piano fingering

involves two simultaneous hands, and must take into account vertical (chords) as well as horizontal (counterpoint) structures, the use of pedals, finger exchanges, and the desired kinds of articulation and phrasing goals [56]. While the most realistic version of the piano fingering problem remains open, the basic DP approach shows promise while allowing for many variations and improvements.

Other interesting examples of fingering problems are found in string instruments such as the guitar and violin. For these instruments, a note is played by choosing a string, a hand position or fret, and the finger to be used, thus giving a wide variety of possible choices for each note. As with the piano, a reasonable measure of fingering quality can be captured by considering only the fingering decisions associated with each pair of adjacent notes. In particular, the penalty function should discourage changes in hand position, large stretches, along with other undesirable traits, as described in Ref. 57 for the case of the guitar. Approaches having a similar spirit could also be applied to breathing on wind instruments as well as bowing for string instruments.

Pitch Structure: Key and Chord Analysis

Key analysis labels a piece of music with a corresponding key or collection of keys. The most simple-minded version of the key finding problem views a musical piece as a “bag of notes” without regard for the notes’ order, duration, simultaneity, and so on. Usually, the notes are further simplified to pitch classes (octave equivalence classes). For these music data, we wish to assign the most plausible key from the 24 possible major and minor keys. Krumhansl and Schmuckler [12] and others have characterized a key in terms of its *pitch profile*—the importance of the pitch classes in a given key, or the proportions with which they occur. Such a profile recognizes a preference for the more fundamental notes, such as the tonic and the scale tones, over other pitch classes. Thus, one could view key estimation as choosing the key whose profile best fits the empirical distribution of pitch classes. Various measures of agreement are used between the empirical distribution of pitch classes

and the pitch profile such as correlation [12], inner product [58], or Kullback-Leibler divergence [39].

However, it is common for music to visit several different keys as it evolves. A more realistic description of the key analysis problem partitions the music into a collection of key-labeled regions [59], say consecutive measures of music. The best explanation of the pitch data would be found by picking a different key for each measure of music. However, this conflicts with our strong preference for key interpretations that do not modulate (change) too much. A compromise approach creates an objective function that measures both, the agreement between the sequence of key labels and the actual musical data, penalizing key changes while rewarding agreement between key and data. Such an objective function fits perfectly into the DP formulation. Any change of key can be seen as a difference between an adjacent pair of key labels, while the data score depends only on the individual labels given to each measure. Thus the objective function is easy to optimize using DP and often results in thoroughly plausible explanations of key activity, as in Ref. 39.

The problem of chord labeling is similar to the problem of key finding. Chords are vertical pitch structures that exist on a more local timescale than key. Because chords change much faster than keys, the problem of segmentation for labeling by region becomes even more important for chords than it is for keys. The sequential nature of data for segmentation makes it particularly amenable to DP approaches. Pardo and Birmingham employ a graph search approach using DP [60], Temperley and Sleater also use DP, but in a rule-based approach [42], and Stoddard and Raphael [61] use an HMM with simultaneous key and chord recognition. In all of these cases, the essential approach is similar to that of key recognition. One difference is that chord knowledge offers more information about pitch profile than does key knowledge, so the chord data models discriminate better between hypotheses. However, this is offset by the greater number of chords that must be considered. Temperley [42] gives an

interesting discussion of the relative merits of these different approaches.

Time Structure: Rhythm Estimation

There are several other aspects of symbolic musical analysis naturally suited to the DP framework. One of the most interesting involves inferences about musical rhythm, made from time sequence (onset) data. Score-writing programs, the musical equivalent of word processors, offer a context in which rhythm recognition would clearly be useful. Here, one would like to play an electronic keyboard, or other MIDI-controlled instrument, into the computer, allowing the program to notate the intended rhythm of the events.

The rhythm estimation problem turns out to be much harder than one might suspect. While one can always choose a rhythm and tempo to approximate an onset sequence to arbitrary precision, the result will almost never be the interpretation the human would choose. Rather, one seeks interpretations that balance faithfulness to the data with *musical plausibility*. This latter trait stems not only from the human preference for simplicity, favoring interpretations of durations as simple fractions of the basic beat, but also from deeper issues of consistency when representing different instances of the same musical figure. A further complication results when tempo changes over time. In this case, one cannot make rhythm assignments without knowing the local tempo, and vice versa, leading to a “chicken-and-egg” problem.

Several authors, such as Cemgil and Kappen [62], Temperley [42], and Raphael [63], address this rhythm estimation problem in various ways. Temperley [42] presents the most straightforward DP-based approach, recovering a sequence of music measure lengths, thus allowing for changing tempo, while ascribing the best rhythmic interpretation of the collection of onset times that lie in the hypothesized measure. Thus, the state in the DP recursion is the time range of the most recently processed measure.

Raphael [63] presents a probabilistic formulation of the problem in terms of two unobserved processes, a Gaussian tempo process

and a discrete process of the musical onset positions of the notes. The computational approach then finds the most likely configuration of both continuous (tempo) and discrete (rhythm) variables using an extension of DP to hybrid state space. Cemgil [62] presents a more sophisticated model than either of the above, not lending itself to DP approaches. Rather, Markov-chain Monte Carlo (MCMC) methods are explored for the actual recognition of the sequence data.

Score Alignment

The previous discussion focused on symbolic music analysis. DP also has applications in audio analysis. The most well-known application of DP here is the *score alignment* problem [64], in which one seeks a correspondence between a symbolic musical score and an audio performance of that score. In essence, one simply wants to know where the score notes occur in the audio. This problem has many possible uses, including the generation of large music audio databases, facilitating quantitative study of musical performance, performance critique, editing of digital music audio, and the coordination of other media, such as animation, with prerecorded music.

Score alignment begins by dividing the audio into a sequence of “frames,” or local snapshots of sounds, as in the frames of a movie. We also can simplify our view of the score, regarding it as a sequence of single notes that will be played in the audio, disregarding any information about notated rhythm. We now seek to label each audio frame with a note from the score, with the constraint that notes must appear in the order prescribed by the score. For instance, if we have three notes in the score, a possible labeling would be $1^i 2^j 3^k$ where $i, j, k \in \mathbb{Z}_+$. One can build a state graph that obeys this constraint simply by allowing each of the possible notes to appear at each frame (level) of the graph, while only allowing a state to remain in the current note or move on to the next note.

A data cost measures the degree to which a particular frame of audio agrees with a particular note in the music score. Most current approaches rely on Fourier analysis. Since pitched musical notes have approximately

periodic signals, we expect to see spectral energy concentrated at frequencies that are integral multiples of the fundamental frequency. There are many possible ways of employing this knowledge to create a data cost for the labeled frame of audio. The cost for an entire path through the state graph can now be constructed as the sum of the costs for each individual frame, thus the arc cost depends only on the state the arc moves to.

Having constructed a graph with arc costs, it is straightforward to use DP to find the minimal cost path through the graph, thus labeling each frame of data with a position in the music score. In fact, this basic idea can be extended to polyphonic music alignment, by viewing the composition as a sequence of chords, rather than single notes. Variations on this basic approach have formed the basis for a number of score alignment efforts, including Refs 65–68.

The HMM has become a popular modeling tool for score alignment researchers in recent years [69–71]. While the approach previously described can be recast as an HMM in which the optimal DP state sequence becomes the maximum a posteriori state sequence, the HMM framework brings other powerful ideas. In this version the audio data becomes the observable part of a hidden Markov chain representing the changing music score position. For instance, a real-time alignment can be constructed using the filtered distribution on the hidden state, while the most likely onset time for a given note can be computed with the forward–backward algorithm.

NASH EQUILIBRIUM (PURE AND MIXED)

MICHAEL A. JONES
Mathematical Reviews, American
Mathematical Society, Ann Arbor,
Michigan

Von Neumann and Morgenstern [1] introduced two distinct, but related approaches to the theory of games. The first approach consisted of two-player, zero-sum games in which the players act simultaneously and independently of one another and the two players' interests are at odds with one another (so that player 2's utility for any outcome of the game is the opposite of player 1's utility for the same outcome). For these games, von Neumann and Morgenstern [1] used the Minimax Theorem [2] (also referred to as the *Fundamental Theorem of Game Theory*—see **Saddlepoints and von Neumann Minimax Theorem**) to determine players' optimal strategies, in which each player's strategy is optimal given the other player's strategy. The second approach consisted of cooperative games in which players can form coalitions and make binding agreements, as well as communicate with one another before and during the game. They analyzed n -player, nonzero sum games by introducing an $(n + 1)$ st player to turn the game into a zero-sum, cooperative game. (See **Cooperative Games with Transferable Utility** and **Cooperative Game Theory with Nontransferable Utility**). Von Neumann and Morgenstern's methods for cooperative games failed to extend optimal strategies to games in which players act simultaneously and independently of one another. These games are called *noncooperative strategic form* (or normal form) games. (Games in which players make their moves sequentially are considered in the sections titled "Noncooperative Extensive-Form (NCEF) Games of Perfect Information" and "Noncooperative Extensive-Form (NCEF) Games of Imperfect Information" in this encyclopedia.)

In Refs 3 and 4, Nash generalized Von Neumann's minimax strategies for strictly competitive, two-player zero-sum games to n -player, noncooperative strategic form games. Like Von Neumann's minimax strategies, Nash's solution concept, now known as the *Nash equilibrium*, allows for mixed strategies, in which players randomize over possible actions. Such a set of strategies (one for each player) is a Nash equilibrium if no player has an incentive to deviate from its strategy when all other players use their strategies in the set. The Nash equilibrium solution concept lends itself to multiple interpretations. If players were instructed to play their portions of a Nash equilibrium strategy, no player would have an incentive not to follow the instructions. Hence, a Nash equilibrium is stable, requiring no binding agreements, as those present in cooperative games. A Nash equilibrium can also be viewed as the stable point of an evolutionary process, as used in evolutionary biology. Holt and Roth [5] discussed the above two interpretations of the Nash equilibrium and its impact on game theory and the social sciences. A Nash equilibrium may also be viewed as the players' optimal responses to their beliefs about the other players' strategies. The variety of useful interpretations of Nash's work was in part the reason why he was awarded the Nobel Prize in Economics in 1994 (along with Harsanyi and Selten).

The next section begins with the definition of noncooperative strategic form games. A discussion of mixed strategies and Von Neumann–Morgenstern utility functions is followed by Nash's theorem of the existence of equilibria (in possibly mixed strategies). Examples in this section highlight canonical two-player games (in which each player has two possible actions) and demonstrate that more than one Nash equilibrium may exist for noncooperative strategic form games. The section concludes with a comparison of Nash equilibria for nonzero and zero-sum games, as well as a stylized view of Nash's work which applies a decomposition of a

two-player, noncooperative strategic form game into a zero-sum game and an equal-payoff game.

Because of the possible multiplicity of Nash equilibria, the number of equilibria in generic noncooperative strategic form games, the construction of games with a unique, pre-specified equilibrium, and the calculation of equilibria are considered in the next section. The article concludes with a description of the attempts to refine the Nash equilibrium concept for noncooperative strategic form games, including perfect and proper equilibria, as well as evolutionary approaches to refinement.

NONCOOPERATIVE STRATEGIC FORM GAMES AND NASH EQUILIBRIA

In a noncooperative strategic form game, players simultaneously and independently select actions or make moves in the game. Each player has a utility or payoff function that defines the player's preferences over the possible outcomes, where each player's goal is to maximize his payoffs, taking into consideration the actions selected by the other players. A formal definition of a noncooperative strategic form game appears below.

Definition 1. An n -player, noncooperative strategic-form game G consists of

- a finite set of players $N = \{1, 2, \dots, n\}$;
- for each player $i \in N$, a nonempty set of possible actions A_i where $A = \times_{i \in N} A_i$ is the set of action profiles;
- for each player $i \in N$, a payoff or utility function $u_i : A \rightarrow \mathbb{R}$ that characterizes player i 's preferences over the action profiles so that player i prefers outcome a to b if and only if $u_i(a) > u_i(b)$;

and is denoted by $G = \langle N, A, u \rangle$ where $u = (u_1, \dots, u_n) : \times_{i \in N} A \rightarrow \mathbb{R}^n$.

If each player's action set A_i is finite, then the game is finite. This article will focus on finite action sets, but will consider a two-player example with an infinite action set.

(For other infinite action spaces, see *Differential Games*). Game theorists have a collection of easy-to-understand games that are part of the vernacular and tradition of game theory because the types of strategic interaction described in these games readily occur in more complex games. These games typically consist of two players, each with a two-element action set. To introduce terminology, a general version of such a game is considered below.

Example 1 [(2 × 2) Bimatrix Games]. A (2×2) bimatrix form game consists of two players. Player 1 (the row player) has action set $A_1 = \{r_1, r_2\}$ where r_i is referred to as row i . Player 2 (the column player) has action set $A_2 = \{c_1, c_2\}$ where c_j is referred to as column j . Because the pair of payoffs for each row and column pair of actions r_i, c_j , $u((r_i, c_j)) = (u_1(r_i, c_j), u_2(r_i, c_j))$, may be arranged in a table or matrix (as in Fig. 1), these games are referred to as *bimatrix games*, or (2×2) bimatrix games in the event that $|A_1| = |A_2| = 2$; two-player, zero-sum games are referred to as *matrix games* (see the section titled “Two-Person Zero-Sum (TPZS) Games” in this encyclopedia).

Each player is aware of all players' possible actions and the associated payoffs, but is unaware of the actions selected by the other players and unaware of the processes used to select the actions. For a bimatrix game, each player is aware of the structure of the bimatrix and its payoffs, aware that the other players are aware, and so on; this is referred to as a *game with perfect information*.

Pure Nash Equilibria

Nash generalized the solution concept of Von Neumann and Morgenstern by considering

		Player 2	
		c_1	c_2
Player 1	r_1	$u_1(r_1, c_1), u_2(r_1, c_1)$	$u_1(r_1, c_2), u_2(r_1, c_2)$
	r_2	$u_1(r_2, c_1), u_2(r_2, c_1)$	$u_1(r_2, c_2), u_2(r_2, c_2)$

Figure 1. General (2×2) bimatrix for a two-player, noncooperative strategic form game.

not just how an individual player should play, but how each player's behavior is a necessary part of an equilibrium profile. The notation (a_i, a_{-i}^*) represents an action profile in which player i plays a_i and all other players play their portion of the action profile $a^* = (a_1^*, \dots, a_n^*)$. Consequently, it follows that $a^* = (a_i^*, a_{-i}^*)$. Below is a definition for an action profile to be a Nash equilibrium.

Definition 2. A Nash equilibrium of a noncooperative strategic form game $G = \langle N, A, u \rangle$ is an action profile $a^* \in A$ such that for every player $i \in N$,

$$u_i(a_i^*, a_{-i}^*) \geq u_i(a_i, a_{-i}^*) \text{ for all } a_i \in A_i.$$

In words, no player i has an action a_i that she prefers to a_i^* when all other players play their respective actions in the profile $a^* = (a_i^*, a_{-i}^*)$.

The action profile a^* has a self-fulfilling property: if all players play their portion of a^* , then no player has an incentive to play anything else. Although compelling from a theoretical viewpoint, the question remained whether or not such equilibria modeled reality. In an effort to determine whether or not the von Neumann and Morgenstern [1] and Nash [3,4] solution concepts were successful in predicting behavior, Flood [6] conducted a series of experiments—part psychology—that formed a foundation for experimental economics and game theory. The most well-known of these was conducted with Dresher [6, Experiment 5: A noncooperative pair]. Albert Tucker later provided a story for this game that came to be known as the *Prisoners' Dilemma*. A stylized story in the spirit of Tucker is given below.

Example 2 [The Prisoners' Dilemma].

Two suspects are found with a bag of money in front of a recently robbed bank. The suspects are taken into custody and separated

so that they do not have time to corroborate a story. Because the police do not have enough evidence to convict the suspects on bank robbery (only possessing the money), the police simultaneously offer the two “prisoners” the following plea bargains. If only one prisoner confesses that the other was the mastermind, then he will receive probation and serve no time while the other will serve a long sentence. If both confess, then they will split the sentence for being coconspirators. If neither confesses, then both prisoners will serve minimal time for the lesser charge of possessing the money. The action of confessing and not confessing are represented by D and C in the Prisoners' Dilemma bimatrix in Fig. 2, respectively, where D stands for “defect” against the other prisoner and C stands for “cooperate” with the other prisoner. The payoffs appear in Fig. 2; recall that the payoffs represent utility and not the amount of time of the sentence.

A short analysis determines that it is in the best interest of each prisoner to defect (play D), regardless of what the other prisoner does. That is, $u_1((D, \cdot)) > u_1((C, \cdot))$ and $u_2((\cdot, D)) > u_2((\cdot, C))$ so that D strictly dominates C . The unique Nash equilibrium is (D, D) . This game is confounding because the Nash equilibrium is inefficient: both players would do better if they were to cooperate and both play C , resulting in (C, C) for which $1 = u_i((C, C)) > u_i((D, D)) = 0$ for both i . Because no agreement can force the players to play (C, C) , both players prefer to play their dominant strategies D , resulting in the Nash equilibrium outcome.

The Prisoners' Dilemma has been used to model diverse strategic situations from nuclear war to trade negotiations. Poundstone [7] provided a popular account of the early history of game theory, the experiment of Flood and Dresher and the ubiquity

	C	D		F	B		H	T		c_1	c_2	
C	1,1	-1,2		F	2,1	0,0	H	1,-1	-1,1	r_1	0,0	1,1
D	2,-1	0,0		B	0,0	1,2	T	-1,1	1,-1	r_2	-1,-1	1,1
Prisoners' Dilemma			Battle of the Sexes			Matching Pennies			Nongeneric Game			

Figure 2. Bimatrix games used in the examples.

of the Prisoners' Dilemma as a model of strategic interaction. Nash's comments about the experiment can be found in Ref. 6 (footnote, p. 24). The players did not play the Nash equilibrium in the experiment. However, the experiment was not a single play of the game. The experiment involved the same two players playing the game repeatedly. Axelrod [8] described a well-known account of a tournament in which players submitted strategies to play the repeated Prisoners' Dilemma. The tournament's winning strategy (garnering the highest utility over games against all other strategies) was tit-for-tat, in which a player plays C initially and continues to do so, unless her opponent defects in round k in which case she responds by playing D in round $k + 1$.

While the Prisoners' Dilemma has a unique Nash equilibrium, the next canonical game demonstrates that there may be more than one Nash equilibrium and that it may be impossible to predetermine which equilibrium is more likely to occur. The following game is referred to as the *Battle of the Sexes* because of the supporting story of a husband and wife (the treatment below is an adaptation of Luce and Raiffa [9, p. 90]). More recent retellings are politically correct (e.g., the equivalent Bach or Stravinsky proposed in Ref. 10).

Example 3 [Battle of the Sexes]. A husband (player 1) and wife (player 2) are to meet up for a night out. Each can go either to the prize fight (F) or the ballet (B). As Luce and Raiffa [9, p. 90] note, "following the usual cultural stereotypes, the man prefers the fight while the woman the ballet; however, to both it is more important that they go out together than that each see the preferred entertainment." Because of a mix-up (and in a time before cell phones), the players are unable to communicate their intentions of which event to attend. The payoffs for the game are given in Fig. 2. There are two Nash equilibrium action profiles: (F, F) and (B, B) with asymmetric payoffs $(2, 1)$ and $(1, 2)$, respectively. It is impossible to presume that either outcome is more likely to occur.

Nash equilibria are stable points, suggesting that players will remain at the equilibrium if starting at the point. Besides the lack of a predictive ability, there is a more troubling occurrence for our current formulation of a Nash equilibrium. Not only do there exist games with multiple equilibria, but there exist games with no equilibrium action profiles (these are referred to as *pure Nash equilibria* below). The following example is a zero-sum game and was used by Von Neumann and Morgenstern [1, p. 94 (Fig. 12); p. 143] in describing the intuition behind mixed strategies (see **Saddlepoints and von Neumann Minimax Theorem**). That same intuition is necessary for nonzero sum, noncooperative strategic form games.

Example 4 [Matching Pennies]. For this bimatrix game (see Fig. 2), let $A_1 = A_2 = \{H, T\}$ where H represents "heads" and T represents "tails." Players 1 and 2 simultaneously each select an action by placing a penny flat on a table (the side facing upward represents the player's strategy). If the coins agree (both H or both T), then (player 1) gets both pennies—and, $u_1((H, H)) = u_1((T, T)) = 1$ while $u_2((H, H)) = u_2((T, T)) = -1$. If the coins do not agree (one is T and the other is H), then player 2 gets both pennies—and, $u_2((T, H)) = u_2((H, T)) = 1$ while $u_1((T, H)) = u_1((H, T)) = -1$. Notice that this game is a zero-sum game (see **Saddlepoints and von Neumann Minimax Theorem**).

Consider the set of four action profiles $A = \{(H, H), (H, T), (T, H), (T, T)\}$. The coins cannot match in equilibrium. This follows because player 2 has an incentive to switch her coin if they do match. However, the coins cannot be mismatched in equilibrium either, as Player 1 will have an incentive to switch his coin so that they agree. Hence, none of the four action profiles is a Nash equilibrium.

In the previous example, players were limited to selecting an action. Allowing players to randomize over their action set provides a richer source of strategies for which there is always a Nash equilibrium (in possibly mixed strategies). However, there are some questions about how mixed strategies should be

interpreted. We will discuss these questions and will return to Matching Pennies in the next section.

Mixed Strategies and Expected Utility

Because a single action may be exploitable (such as playing H in Matching Pennies), a mixed strategy allows a player to select randomly an action according to a probability distribution. It is easy to extend mathematically the definition of a strategy to include lotteries over actions. However, in practice, people do not make decisions according to the outcome of such a lottery (and would find it hard to implement the selection of an action without the help of an external device such as a computer or a coin to flip).

To resolve these types of concerns for how players randomize over their actions, Aumann and Brandenburger [11] viewed a Nash equilibrium as a collection of optimal responses to the players' beliefs over the other players' strategies. In this framework, each player (e.g., a player in Matching Pennies) realizes that his opponent is drawn from a population of possible game players. Each player in the population of game players plays a single action, but the player chooses her behavior to optimize over her belief about the probability distribution of her opponents and consequently, the probability distribution of the opponents' actions—which is just a mixed strategy profile σ_{-i} . Further interpretations of mixed strategies (and mixed strategy equilibria) are considered later in this section (and can be found in Binmore's collection of essays [12]).

Definition 3. A mixed strategy for player i is a probability distribution $\sigma_i = (\sigma_{i,1}, \sigma_{i,2}, \dots, \sigma_{i,m_i})$ over $A_i = \{a_{i,1}, a_{i,2}, \dots, a_{i,m_i}\}$ where $\sigma_{i,j} \geq 0$ is the probability that player i places on action $a_{i,j}$ so that $\sum_{j=1}^{m_i} \sigma_{i,j} = 1$. Let Σ_i be the set of all mixed strategies of player i . A mixed strategy profile $\sigma = (\sigma_1, \dots, \sigma_n)$ is a vector of players' mixed strategies.

The set of mixed strategies contains the set of pure strategies (equivalent to the set of action profiles); hence, a pure strategy for

player i is a mixed strategy in which $\sigma_i = (\sigma_{i,1}, \dots, \sigma_{i,m_i})$ has $\sigma_{i,j} = 1$ for some j and $\sigma_{i,k} = 0$ for all $k \neq j$. To simplify notation in (2×2) bimatrix games, let the mixed strategy profile $((p, 1-p), (q, 1-q))$ —in which player 1 places probabilities p and $1-p$ on r_1 and r_2 , respectively, and player 2 places probabilities q and $1-q$ on c_1 and c_2 , respectively—be represented by (p, q) . For a mixed strategy profile σ and an action profile $a \in A$, let $\sigma_j(a)$ be the probability that player j places on its portion a_j of the action profile a . It follows that $\sigma_j(a) = \sigma_{j,k}$ when player j 's component of a is $a_{j,k}$. Hence, for $a = (a_1, \dots, a_n) \in A$, $\prod_{j=1}^n \sigma_j(a)$ is the probability that action a is played under σ .

As part of the foundation for game theory, Von Neumann and Morgenstern [1] described how to account for the uncertainties of players' actions in mixed strategies by considering the players' utilities of lotteries (probability distributions) over outcomes. Payoffs indicating preferences of action profiles had to be extended to preferences of lotteries over action profiles. Von Neumann and Morgenstern [1] provided a set of axioms so that a player's preferences of lotteries could be described by the expected value of a (Von Neumann–Morgenstern) utility function. In what follows, all utility functions are assumed to be Von Neumann–Morgenstern utility functions. And, for consistency, assume that the payoffs in the previous examples are described by such utility functions.

Definition 4. The expected utility for player i under the mixed strategy profile σ is

$$u_i(\sigma) = \sum_{a \in A} \left(\prod_{j=1}^n \sigma_j(a) \right) u_i(a).$$

Using words to describe Definition 4, player i 's expected utility is the sum of i 's utility under every action profile weighted by the probability that the particular action profile occurs. If all players use a pure strategy under σ' , then, for one $a' \in A$, the product $\prod_{j=1}^n \sigma_j(a') = 1$ while for all other $a \in A$, $\prod_{j=1}^n \sigma_j(a) = 0$. It follows that

$$u_i(\sigma') = \sum_{a \in A} \left(\prod_{j=1}^n \sigma_j'(a) \right) u_i(a) = u_i(a').$$

Hence, the expected utility function for a pure strategy profile returns the utility function that describes preferences over actions in Definition 1.

Mixed Strategy Nash Equilibria

By allowing players to use mixed strategies, players' payoffs had to be defined in terms of Von Neumann–Morgenstern utilities. It follows that the definition of a Nash equilibrium must be redefined, as well.

Definition 5. A mixed strategy σ^* for a non-cooperative strategic form game $\langle N, A, u \rangle$ is a Nash equilibrium if, for all players i ,

$$\begin{aligned} u_i(\sigma_i^*, \sigma_{-i}^*) &\geq u_i(\sigma_i, \sigma_{-i}^*) \\ &\text{for all } \sigma_i \in \Sigma_i, \text{ or, equivalently,} \\ u_i(\sigma_i^*, \sigma_{-i}^*) &\geq u_i(s_i, \sigma_{-i}^*) \\ &\text{for all pure strategies } s_i. \end{aligned}$$

The first of the two equivalent inequalities mimics the requirements for an action profile to be a Nash equilibrium from Definition 2. However, it is the second inequality that is preferred and easier to apply. To see that these are equivalent, suppose that the first inequality holds. Because a pure strategy is by default a mixed strategy, then the second inequality is satisfied as well. Now suppose that the second inequality holds but that the first does not. Then at least one player i has a mixed strategy profile τ_i in which his expected payoff is greater than under σ_i^* . Because $u_i(\tau_i, \sigma_{-i}^*)$ is a convex combination (from the probability distribution τ_i over the pure strategies) of the payoffs for player i under pure strategies, then at least one of the pure strategies must have a greater payoff for player i than $u_i(\sigma_i^*, \sigma_{-i}^*)$, contradicting the second inequality of Definition 5.

For a Nash equilibrium σ^* , the support S_i of σ_i^* is the subset of A_i for which σ_i^* places positive probability. An important consequence of the definition of a mixed strategy

Nash equilibrium is that the expected utility of playing the pure strategy s_i that places probability 1 on $a_i \in S_i$ versus σ_{-i}^* is equal to the expected utility under σ_i^* . If it were less, then player i would do better to decrease the weight on a_i to 0. If it were more, then player i would do better to increase the weight on a_i to 1. In particular, this shows that positive probability is never placed on a dominated strategy. In later sections, the payoff under an action that receives positive probability in a mixed strategy Nash equilibrium is revisited in the discussion of an algebraic proof of the existence of a Nash equilibrium, as well as in describing how to calculate equilibria.

As a criticism of mixed strategies, realize that the outcome of a play of a game (often referred to as a *single-shot game*) is some action profile $a \in A$. Even when players play a mixed strategy Nash equilibrium σ^* , the outcome a of their mixed strategy may not be a Nash equilibrium action profile—and most likely will not be. The fact that $u_i(s_i, \sigma_{-i}^*) = u_i(\sigma_i^*, \sigma_{-i}^*)$ for a pure strategy s_i that places positive probability on the support of σ_i^* is now problematic. If the player receives the same expected payoff using any pure strategy on any action in the support of the mixed strategy Nash equilibrium, then there is impetus for a player to play one of these pure strategies instead. For that matter, any probability distribution of the support of the mixed strategy Nash equilibrium yields that same expected payoff! Besides Aumann and Brandenburger's description [11] of mixed strategies in terms of beliefs, others have considered reformulations of mixed strategies in an effort to justify their use. For example, in what is known as the *purification problem*, Harsanyi [13] interpreted mixed strategies as the result of limiting (pure) strategies of perturbed games based on players' knowledge of the payoffs, in which each player knows his own payoffs but not his opponents' payoffs.

Example 5 [Matching Pennies—Revisited]. Recall the payoffs for Matching Pennies in Fig. 2 and the discussion of the game in Example 4. Assume that player 2 plays H more frequently than T in the mixed strategy $(q, 1 - q)$. Player 1's expected payoff for playing H is $u_1((1, q)) = q + (-1)(1 - q) =$

$2q - 1$ while his expected payoff under T is $u_1((0, q)) = -1q + 1(1 - q) = 1 - 2q$. Because $q > 1/2$, player 1 can exploit player 2's mixed strategy by always playing H (or $p = 1$). The situation is reversed if player 2 uses $q < 1/2$ —that is, player 1 can exploit player 2's strategy by playing T with certainty. The only value of q for which player 1 cannot exploit player 2's strategy is $q = 1/2$. This can be seen by equating the payoffs that player 1 would receive under H and T or $2q - 1 = 1 - 2q$ and solving for q . The asymmetric payoffs suggest that $p = q = 1/2$ is a mixed strategy Nash equilibrium. This is verified because $\sigma^* = (\sigma_1^*, \sigma_2^*) = ((1/2, 1/2))$ (where the first $1/2$ is p and the second $1/2$ is q) satisfies

$$0 = u_i(\sigma^*) \geq u_i(s_i, \sigma_{-i}^*) \text{ for all pure strategies } s_i \in \Sigma_i \text{ for both players } i.$$

Intuition present in Matching Pennies was necessary to make an educated guess about a mixed strategy Nash equilibrium. That mixed strategy Nash equilibria exist in general requires a more systematic approach. We will apply the idea behind Nash's proof [3] of the existence of Nash equilibria to determine all the Nash equilibria for different (2×2) bimatrix games. This idea requires the definition of a correspondence or point-to-set mapping f where $f : \Sigma \rightrightarrows \Omega$ satisfies $f(\sigma) \subseteq \Omega$ for all $\sigma \in \Sigma$.

Definition 6. The best-response correspondence for player i in the game $G = \langle N, A, u \rangle$ is the point-to-set correspondence $BR_i : \times_{j \neq i} \Sigma_j \rightrightarrows \Sigma_i$ where

$$BR_i(\sigma_{-i}) = \{\sigma_i \mid \sigma_i \in \Sigma_i \text{ such that } u_i(\sigma_i, \sigma_{-i}) \geq u_i(\tau_i, \sigma_{-i}) \text{ for all } \tau_i \in \Sigma_i\}.$$

The best-response correspondence for player i returns the set of strategies that maximizes player i 's payoff when the other players play σ_{-i} . Nash's insight was to apply a fixed point theorem to the best-response correspondence

$$BR = (BR_1, \dots, BR_n) : \times_{i \in N} \Sigma_i \rightrightarrows \times_{i \in N} \Sigma_i.$$

A mixed strategy profile σ^* is a fixed point of the best response correspondence BR (so that $BR(\sigma^*) = \sigma^*$) when no player i can increase his expected payoff by deviating from σ_i^* when the other players play σ_{-i}^* . But this is exactly the definition of a mixed strategy Nash equilibrium (Definition 5).

Theorem 1 [Nash [3]]. *Every finite non-cooperative strategic form game has a mixed strategy equilibrium.*

Nash [3] demonstrated that a fixed point theorem of Kakutani was applicable to the best-response correspondences of finite non-cooperative strategic form games. Nash also provided a different, more involved proof of the existence of Nash equilibria for finite, n -player games using the Brouwer fixed point theorem in Ref. 4 that required defining an appropriate continuous function, a fixed point of which is also a Nash equilibrium. The following version of Kakutani's theorem is adapted from Ref. 14, which refers to upper hemi-continuity as the closed graph property because the set of (σ, τ) where $\tau \in f(\sigma)$ is closed. Upper hemi-continuity is also referred to as *upper semicontinuity* (including in Ref. 15).

Theorem 2 [Kakutani [15]]. *Let Σ be a compact, convex, nonempty subset of $\mathbb{R}^n$. Let f be a point-to-set correspondence $f : \Sigma \rightrightarrows \Sigma$ such that*

1. $f(\sigma)$ is nonempty for all σ ,
2. $f(\sigma)$ is convex for all σ ,
3. f is upper hemi-continuous (i.e., if σ_n converges to σ^* , τ_n converges to τ^* such that $\tau_n \in f(\sigma_n)$, then $\tau^* \in f(\sigma^*)$).

Then, there exists at least one $\sigma^ \in \Sigma$ such that $\sigma^* \in f(\sigma^*)$.*

The following sketch of the application of Kakutani's theorem follows Fudenberg and Tirole's proof [14]. Further, Myerson [16] gives a lengthy discussion of the application of Kakutani's fixed point theorem to prove Nash's theorem.

Proof. (Sketch for Theorem 1; Nash [3]) To apply Kakutani's theorem, define $\Sigma = \times_{i \in N} \Sigma_i$. Because each Σ_i is an $(m_i - 1)$ -simplex (that is, nonnegative vectors in $\mathbb{R}^{m_i}$ whose entries sum to 1), then Σ is compact, convex, and nonempty. The set $BR(\sigma)$ is nonempty because each player's payoff function is linear (and hence continuous) over the compact simplex of mixed strategies, and continuous functions attain their extrema on compact sets. The set $BR(\sigma)$ is convex if for any $\sigma', \sigma'' \in BR(\sigma)$, then $\alpha\sigma' + (1 - \alpha)\sigma''$ is also in $BR(\sigma)$. This follows due to the definition of best response and expected utility for each player i because $u_i(\sigma'_i, \sigma_{-i}) = u_i(\sigma''_i, \sigma_{-i}) = \alpha u_i(\sigma'_i, \sigma_{-i}) + (1 - \alpha)u_i(\sigma''_i, \sigma_{-i}) = u_i(\alpha\sigma' + (1 - \alpha)\sigma'', \sigma_{-i})$. The upper hemi-continuity of BR can be proved by contradiction and relies on the continuity of the u_i 's. Hence, BR satisfies the conditions of Kakutani's theorem—there exists a fixed point of BR , which is a Nash equilibrium.

To demonstrate the application of Kakutani's theorem with best-response correspondences from a (2×2) bimatrix game, we return to the Battle of Sexes.

Example 6 [Battle of the Sexes—Revisited]. Recall the bimatrix form of the Battle of the Sexes from Fig. 2. Let (p, q) represent a mixed strategy profile in which player 1 places probability p on F and player 2 places probability q on F . The best-response correspondence for player 1 is derived as follows. For player 2 playing q , player 1 prefers to play F when the expected value under F is greater

than under B , that is, $u_1((1, q)) > u_1((0, q))$ or $2q > 1 - q$ which reduces to $q > 1/3$. Hence, player 1's best response to $q > 1/3$ is to play F with probability 1 or $p = 1$. It follows that player 1 prefers B when $q < 1/3$ and is indifferent between any mixture of F and B when $q = 1/3$. This information gives us the best-response correspondence for player 1. A similar approach can be used to determine the best-response correspondence of player 2.

$$BR_1(q) = \begin{cases} \{0\} & \text{if } q < 1/3 \\ [0, 1] & \text{if } q = 1/3 \\ \{1\} & \text{if } q > 1/3 \end{cases}$$

$$BR_2(p) = \begin{cases} \{0\} & \text{if } p < 2/3 \\ [0, 1] & \text{if } p = 2/3 \\ \{1\} & \text{if } p > 2/3 \end{cases}$$

Since $p \in [0, 1] = \Sigma_1$ and $q \in [0, 1] = \Sigma_2$, then $\Sigma = \Sigma_1 \times \Sigma_2$ is the set of mixed strategies for the Battle of the Sexes. The graph of player 1's best-response correspondence $\{(x, q) \mid x \in BR_1(q) \text{ for all } q\}$ appears in the left of Fig. 3. Similarly, the graph of player 2's best-response correspondence $\{(p, y) \mid y \in BR_2(p) \text{ for all } p\}$ appears in the middle of Fig. 3. The intersection of these two sets is $\{(0, 0), (1, 1), (2/3, 1/3)\}$ and appears in the right of Fig. 3. For $\sigma^* = (\sigma_1^*, \sigma_2^*) \in \{(0, 0), (1, 1), (2/3, 1/3)\}$, it follows that $\sigma_1^* \in BR_1(\sigma_2^*)$ and $\sigma_2^* \in BR_2(\sigma_1^*)$. Hence, each σ^* is a Nash equilibrium.

Two of the three Nash equilibria for the Battle of the Sexes were determined previously in Example 3. Naturally, the mixed

Figure 3. Best-response correspondences for player 1 (left) and player 2 (middle). Graphed together (right), their intersections yield three Nash equilibria in the Battle of the Sexes (Example 6).

strategy Nash equilibrium was not considered before. Example 6 demonstrates that a game may have both pure and mixed strategy Nash equilibria. Matching Pennies demonstrates that there may only be a single Nash equilibrium in mixed strategies, while the Prisoners' Dilemma does the same for pure strategies. The following example shows that a game need not have only a finite number of equilibria.

Example 7 [Infinite Number of Equilibria]. Consider the nongeneric game in Fig. 2. Again, let mixed strategy profiles be denoted by (p, q) . The best-response correspondences are

$$BR_1(q) = \begin{cases} [0, 1] & \text{if } q = 0 \\ \{1\} & \text{if } q > 0. \end{cases} \quad BR_2(p) = \{0\},$$

which are represented as graphs in Fig. 4. It follows that $\{(p, 0) \mid p \in [0, 1]\}$ are all Nash equilibria. Because player 1 weakly prefers r_1 to r_2 regardless of the value of q , the Nash equilibrium $(1, 0)$ seems more likely to occur in practice.

Besides showing that there may be an infinite number of equilibria, the previous example suggests that perhaps other secondary characteristics may be useful to narrow further the set of Nash equilibria. Referring to the game in Example 7 as “nongeneric” is not an accident. When the payoffs for games are drawn from continuous distributions over intervals of real numbers, finite noncooperative strategic form games

have a finite number of equilibria except for an exceptional set of payoffs whose closure has Lebesgue measure zero. A property that is satisfied for all games up to a set of measure zero is referred to as *generic*. Most proofs that generic games have a finite number of equilibria were provided en route to establishing an algorithm to construct or to approximate equilibria. However, Govindan and Wilson [17] provided a direct proof. The number of equilibria is considered below in the section titled “Counting, Constructing, and Calculating Nash Equilibria.” Refining the set of Nash equilibria by considering additional characteristics is discussed in the section titled “Refinements of Nash Equilibria for Strategic Form Games.”

The following game demonstrates that additional requirements are necessary to ensure that there exists a Nash equilibrium when the action sets of the players are not finite.

Example 8 [Race to the Bottom]. For a two-player noncooperative strategic form game, let $A_1 = A_2 = \mathbb{Q}^+$ (the positive rational numbers). For positive rational numbers q_1 and q_2 , the payoffs in the zero-sum game are described by the utility functions

$$\begin{aligned} u_1((q_1, q_2)) &= -u_2((q_1, q_2)) \\ &= \begin{cases} 1 & \text{if } q_1 < q_2 \\ 0 & \text{if } q_1 = q_2 \\ -1 & \text{if } q_1 > q_2 \end{cases} . \end{aligned}$$

Suppose that player 2's mixed strategy σ_2 places positive probability on a finite set

Figure 4. Best-response correspondences for player 1 (left) and player 2 (middle). Graphed together (right), their intersections (circled) yield infinitely many Nash equilibria for the nongeneric game (Example 7).

$Q_2 \subset \mathbb{Q}^+$. Then, player 1's best-response to σ_2 , $BR_1(\sigma_2)$, is the set of mixed strategies over $(0, q_*) \cap \mathbb{Q}^+$ where q_* is the minimum rational number in Q_2 . However, if player 2's mixed strategy has infinite support with no minimum value, then player 1 has no best response. For example, if σ'_2 places probability $1/2^n$ on $1/2^n$ for positive integers n , then $BR_1(\sigma'_2) = \emptyset$. Each player prefers to use rational numbers closer and closer to zero. Because there is no smallest positive rational number, then there is no Nash equilibrium.

Noncooperative strategic form games with infinite action spaces are covered in the articles titled in **Differential Games** in this encyclopedia. Below we examine some properties of Nash equilibria for zero-sum games and consider a stylized view of Nash equilibria for two-player, noncooperative strategic form games.

Nash Equilibria for Zero-Sum Games and a Decomposition of Bimatrix Games

As remarked by Nash in Refs 3, 4, his theorem reduces to the Minimax Theorem [2] when applied to zero-sum or matrix games. Not only do minimax/maximin strategies for zero-sum games satisfy the aforementioned properties of Nash equilibria, but additional properties as well. These properties are reviewed and compared to Nash equilibria for nonzero sum games below.

For a two-player, zero-sum game, the entries $(u, -u)$ of the bimatrix sum to zero. If $u > 0$, then Player 1 receives u and Player 2 loses u (which can be thought of as Player 2 paying Player 1); this relationship of who pays whom changes if $u < 0$. A strategy σ_1^* for player 1 is a maximin strategy if it maximizes the minimum payoff of player 1 (over player 2's strategies) while a strategy σ_2^* for player 2 is a minimax strategy if it minimizes the maximum payoff that player 2 pays to player 1 (over player 1's strategies). In the Minimax Theorem, Von Neumann [2] showed that minimax and maximin strategies always exist for zero-sum games with finite actions; see the article titled **Saddlepoints and von Neumann Minimax Theorem** in this encyclopedia.

Both σ_1^* and σ_2^* may be viewed as security strategies (see Ref. 18 for misconceptions about the optimality of minimax strategies) for which a value v is associated so that player 1 can be guaranteed a payoff of at least v and in which player 2 can be guaranteed to lose no more than v . The payoff v to player 1 under σ^* is referred to as the *value of the game*. Of course, $\sigma^* = (\sigma_1^*, \sigma_2^*)$ is a Nash equilibrium. As with Nash equilibria for nonzero sum games, there may be more than one Nash equilibrium for a zero-sum game. However, each Nash equilibrium strategy profile yields the same value so that a matrix game's value is well-defined. This is in sharp contrast to nonzero sum games in which the payoffs to the players depends on which equilibrium is played (as in the Battle of the Sexes, Example 6). For zero-sum games, there is no coordination problem of determining which equilibrium should be played, as all equilibria result in the same value. Further, each pair of maximin and minimax strategies combine to form a Nash equilibrium. For these reasons, Nash equilibrium strategies are referred to as *exchangeable*. See the section titled "Two-Person Zero-Sum (TPZS) Games" in this encyclopedia for more information.

For finite, bimatrix games, the existence of Nash equilibria may be viewed as an extension of the equilibrium concept from a subspace of zero-sum games to a larger space. A bimatrix game can be decomposed into the sum of an equal-payoff symmetric game (in which the payoff for each player is the same) and a zero-sum game. These form the two extremes in which players payoffs are completely aligned and completely opposed, respectively. The discussion will be limited to (2×2) bimatrix games but extends to $(m \times n)$ bimatrix games. The decomposition is presented below. This decomposition was used by Nash [19] in developing his two-person bargaining solution using players' threat strategies (a description of which appeared in Shubik [20])—see the article titled **Cooperative Games with Transferable Utility** in this encyclopedia.

Example 9 [(2 × 2) Bimatrix Games—Revisited]. Let (a, b, c, d, e, f, g, h) represent the utilities of the bimatrix game in Fig. 5.

$$\begin{array}{|c|c|} \hline a,b & c,d \\ \hline e,f & g,h \\ \hline \end{array} = \begin{array}{|c|c|} \hline \frac{a+b}{2}, \frac{a+b}{2} & \frac{c+d}{2}, \frac{c+d}{2} \\ \hline \frac{e+f}{2}, \frac{e+f}{2} & \frac{g+h}{2}, \frac{g+h}{2} \\ \hline \end{array} + \begin{array}{|c|c|} \hline \frac{a-b}{2}, \frac{b-a}{2} & \frac{c-d}{2}, \frac{d-c}{2} \\ \hline \frac{e-f}{2}, \frac{f-e}{2} & \frac{g-h}{2}, \frac{h-g}{2} \\ \hline \end{array}$$

(2 × 2) Bimatrix game
Equal-payoff game
Zero-sum game

Figure 5. Decomposition of a general (2 × 2) bimatrix into zero-sum and equal-payoff symmetric games.

The space of all (2 × 2) bimatrix games is of dimension eight—one dimension for each of the eight parameters in (a, b, c, d, e, f, g, h) . Figure 5 demonstrates a decomposition of a general bimatrix form game into a component in the equal-payoffs subspace and a component in the zero-sum game subspace. These orthogonal subspaces each have dimension four.

An equal-payoff game is reminiscent of a decision theory problem, as both players have the same incentives. (And, in fact, it is easy to predict an outcome when there is a single entry in the bimatrix with the largest value. However, in such a case, there may be more than one Nash equilibrium, even if there is a single, largest entry.) Quint and Shubik [21] referred to these equal-payoff games as coordination games and gave bounds on the number of Nash equilibria for such games. The nonzero sum, noncooperative strategic form game also has a zero-sum game component. A conceptual view of Nash's theorem for bimatrix games is that it proves the existence of equilibria for the extremes cases of no conflict and total conflict games, and everywhere in between.

CLASSIFICATION OF EQUILIBRIA FOR NON-COOPERATIVE STRATEGIC FORM GAMES

After Nash [3,4] provided the proof of the existence of equilibria for nonzero sum, finite noncooperative strategic form games, the question turned to characterizing Nash equilibria. Ideally there would be a single Nash equilibrium. However, as demonstrated in the previous examples, there may be more than one equilibrium, even infinitely many. Further, pure and mixed strategies may exist

concurrently, or separately. To determine what may happen, researchers focused on counting, constructing, and calculating equilibria. These results are considered below.

For the instances in which there are more than one Nash equilibrium, the question of whether any of the equilibria may be eliminated (as infinitely many of the equilibria in Example 7 were viewed as specious) by considering additional qualifications is known as *equilibrium refinement*. The section on equilibrium refinement and evolutionary game theory does not attempt to be comprehensive, but to provide a sample of the types of results that are possible.

Counting, Constructing, and Calculating Nash Equilibria

For a finite, noncooperative strategic form game, let $m_i = |A_i|$ for all $i \in N$. From the discussion following the definition of a mixed strategy Nash equilibrium (Definition 5), it follows that $u_i(\sigma_i^*, \sigma_{-i}^*) = u_i(s_i, \sigma_{-i}^*)$ where s_i places probability 1 on an action a_i in the support S_i of σ_i^* . Reverse engineering this fact, one can determine Nash equilibria by solving systems of equations that are based on the support of a possible mixed strategy Nash equilibrium. For each player, there are $2^{m_i} - 1$ possible sets of actions that may be the support of a Nash equilibrium. Considering the possible supports for all players, there are $\prod_{i=1}^n (2^{m_i} - 1)$ systems of equations to solve. If a solution to a system of equations yields a probability distribution over each player's support, then the result is a Nash equilibrium. If each player i 's support is A_i for a mixed strategy profile, then the profile is totally mixed. For two players, the resulting linear equations have at most one solution, so there is only one totally mixed Nash equilibrium strategy profile (unless the game is

nongeneric). For more than two players, the equations are nonlinear and can have a multitude of solutions. McKelvey and McLennan [22] provided a 10-player game with more than a million totally mixed Nash equilibria where each player has two strategies. Datta [23] described the complexity of the nongeneric case using algebraic geometry.

Nash's two proofs of the existence of equilibria for finite, n -player games [3,4] were based on fixed point theorems. Just as the Minimax Theorem is an algebraic theorem—Weyl [24] and Gale *et al.* [25] provided algebraic proofs of the existence of equilibria for finite, two-player zero-sum games—so, too, is the existence of Nash equilibria: solving for the weights of the probability distributions in the aforementioned systems of equations. Lemke and Howson [26] were the first to prove the algebraic existence of equilibria for two-player, finite strategic form games by a constructive method related to linear programming; they proved that generic bimatrix games have an odd number of equilibria (and so there cannot be zero equilibria). Rosenmüller [27] and Wilson [28] extended the Lemke–Howson approach to prove that there are an odd number of Nash equilibria in generic n -player, finite strategic form games. Harsanyi [29] provided an alternate proof, while Govindan and Wilson's proof [17] was not the consequence of an algorithm to compute equilibria.

If a game only has a single Nash equilibrium, then there is no need to evaluate or to compare the equilibrium. Hence, some research focused on how likely it is for there to be a unique Nash equilibrium. More generally, research concentrated on determining the distribution of the number of equilibria, constructing games with a specific equilibrium, and bounding the number of equilibria.

Goldberg *et al.* [30] focused on the likelihood that a two-player, noncooperative strategic form game has a single, pure strategy Nash equilibrium and showed that this probability converges to $1 - 1/e$ as the numbers of actions of the players increase without bound. This result was extended by Dresher [31] for games with more than two players, again showing that the probability of there being a single, pure strategy Nash

equilibrium converges to $1 - 1/e$ as two or more of the numbers of actions of the players increase without bound. For n -player noncooperative strategic form games with a countable number of actions, Powers [32] proved that the distribution of the number of pure strategy Nash equilibria approaches the Poisson distribution with mean 1 as the numbers of strategies of two or more players go to infinity; Stanford [33] provided a simpler proof.

Additional work has focused on the uniqueness of a mixed strategy Nash equilibrium. For bimatrix games, Kreps [34], Heuer [35], and Quintas [36] constructed games that would have a specified mixed strategy profile as its unique Nash equilibrium. A mixed strategy profile (σ_1^*, σ_2^*) can be the unique Nash equilibrium if the support of σ_1^* and σ_2^* is the same size. Kreps [37] determined conditions for the uniqueness of totally mixed strategies in n -player games, as well as constructed payoffs for a game with a given unique, totally mixed Nash equilibrium.

Quint and Shubik [38] showed that for any odd integer m between 1 and $2n - 1$, there is an $n \times n$ bimatrix game with exactly m Nash equilibria—their proof relies on an existence result on weighted majority cooperative games—and conjectured that a generic $m \times m$ bimatrix game could have at most $2^m - 1$ Nash equilibria. Von Stengel [39] provided a counterexample for $m = 6$ with 75 Nash equilibria and showed how to extend the construction for $m > 6$. Quint and Shubik [21] proved that their conjectured bound of a maximum of $2^m - 1$ Nash equilibria does hold for a class of coordination games (the equal-payoff games of the section titled “Nash Equilibria for Zero-Sum Games and a Decomposition of Bimatrix Games”).

Von Stengel [39] also computed new lower bounds for the maximum number of equilibria in an $(m \times m)$ bimatrix game. McLennan and Berg [40] determined the expected number, asymptotically in the number of actions, of Nash equilibria for bimatrix games under the assumption that the players' payoffs are identically and independently distributed normal random variables with mean zero. Under different probabilistic assumptions, McLennan [41] addressed the question of the expected number of Nash equilibria

for n -player games. For more on equilibrium computation, see von Stengel's survey [42].

Brown [43] proposed a simple iterative method for approximating the solutions of zero-sum, two-player games that Robinson [44] proved converges to a Nash equilibrium of the game. This type of fictitious play was a precursor to evolutionary biological and evolutionary dynamics approaches to game theory. Evolutionary stability is viewed as an equilibrium refinement below. The Nash equilibria for modest-sized noncooperative strategic form games can be calculated through Gambit [45], a freely available game theory solver. The application of Gambit, as well as code for the computer algebra systems Mathematica and Maple, to compute Nash equilibria is demonstrated in the game theory book by Barron [46].

Refinements of Nash Equilibria for Strategic Form Games

From the examples of (2×2) bimatrix games, there may be more than one Nash equilibrium for a finite, noncooperative strategic form game. The idea behind equilibrium refinement is to consider additional criteria to disqualify some of the Nash equilibria. An important criterion is whether or not the refinements always exist.

Selten [47] introduced perfect (also called *trembling-hand perfect*) equilibria, which he showed always exist for finite, noncooperative strategic form games, as a refinement of the set of Nash equilibria. A perfect equilibrium may be viewed as the limit of a totally mixed strategy profile for which a minimum positive probability must be placed on each action. This minimum weight can be viewed as a tremble or mistake by a player. Hence, a Nash equilibrium is a perfect equilibrium if it is stable or robust in the presence of small trembles or perturbations. Three formulations of perfect equilibria are proved to be equivalent in the text by Fudenberg and Tirole [14, p. 351]. One of these equivalent formulations is to define perfect equilibria as the limit of Nash equilibria in some sequence of constrained games. All three formulations define perfect equilibria as the limit of *some* sequence of totally mixed strategies, as opposed to *all*

such sequences. Perfect equilibria may also be defined for extensive form games and are related to sequential equilibria, a refinement of Nash equilibria for extensive-form games. For refinements of extensive form games, see the sections titled "Non-Cooperative Extensive-Form (NCEF) Games of Perfect Information" and "Non-Cooperative Extensive-Form (NCEF) Games of Imperfect Information" in this encyclopedia.

Myerson [48] introduced proper equilibria as a refinement of perfect equilibria. In this case, trembles are adjusted according to how severe the mistake would be (according to the payoff function). A minor mistake is more likely to be made than a costly mistake; more specifically, a player's n th-best actions are played with at most ε probability of her $(n - 1)$ st-best actions. In this sense, trembles are rational. Myerson showed that the set of proper equilibria is a nonempty subset of perfect equilibria, which makes sense as the types of trembles are more restricted than under perfect equilibria and provide a sequence for limit definitions of perfect equilibria. Myerson [48] showed that proper equilibria always exist for finite noncooperative strategic form games. Halpern [49] characterized the proper equilibrium refinement for noncooperative strategic form games in terms of nonstandard probability. For more information on refinements, see other articles in this encyclopedia.

Perfect and proper equilibria may be viewed as robust against certain types of mutations of the strategies. Evolutionary game theory studies evolutionary processes that are governed by a mutation mechanism as well as a selection mechanism that rewards successful strategies in a next generation (see Weibull [50, p. 69]). The mutation mechanism is embodied by notions of evolutionary stability, while the selection mechanism is governed by dynamic processes that update the population levels. For these games, a mixed strategy represents the percentages of the population that play the associated pure strategies. Members of the populations are matched at random to play the game, often restricted to two species or populations. In some cases, the players within a population are playing against

one another and have the same ordered action sets so that the resulting $(n \times n)$ bimatrix game has symmetric payoffs where $u_1(r_i, c_j) = u_2(r_j, c_i)$ for all $i, j \in \{1, \dots, n\}$. However, evolutionary game theory is not limited to symmetric, bimatrix games.

Biologist Maynard Smith [51] introduced evolutionary stable strategies (ESSs) based on the ability of a population (of game players using the same pure strategy) to survive against a mutation. Because the biological underpinnings require specific relationships between payoffs, an ESS is not well-defined for all noncooperative strategic form games. An ESS (if one exists) is by definition a Nash equilibrium, but if there is another best-reply (like the pure strategies in the support of a mixed strategy Nash equilibrium) strategy, then the ESS must receive a higher payoff against the other strategy than the other strategy does against itself. This prevents the new strategy from gaining a foothold in the population. To give a sample of the relationship between an ESS and other topics considered in this article, if the set of ESS for a finite, noncooperative strategic form game is finite and there is a totally mixed ESS, then the set consists only of this totally mixed strategy. For more information on ESSs, see the text by Hofbauer and Sigmund [52].

Another possibly empty refinement of Nash equilibria is an equilibrium evolutionary stable (EES) set. Weibull [50, p. 168] described an EES set as “a minimal closed set of Nash equilibria such that no small-scale invasion of equilibrium entrants can lead the population out of the set.” Equilibrium entrants introduce a type of rational mutation. For bimatrix games, Swinkels [53] showed that a nonempty EES set contains a proper equilibrium.

Selection processes reward successful pure strategies with a greater payoff that allows them to reproduce (or replicate) more successfully in the population by assuming that the strategy is passed on to offspring, thereby increasing the percentage of the population playing the strategy. The most common selection or dynamic process is called *replicator dynamics*, introduced by Taylor and Jonker [54], in which reproduction takes place continuously over time and

the dynamics are represented by a system of differential equations. For a population playing an evolutionary game against other members of the population, the mixed strategy profile $p = (p_1, \dots, p_n)$ describes the distribution of a population so that p_i of the population plays the pure strategy s_i that places probability 1 on action a_i . Each p_i is viewed as a function of time t so that the population evolves according to

$$\frac{dp_i(t)}{dt} = [u_i(s_i, p) - u_i(p, p)]p_i(t),$$

where the difference $u_i(s_i, p) - u_i(p, p)$ indicates how well the pure strategy s_i does in payoff compared to the population p on average. When the difference is positive, then the population playing s_i grows because its derivative is positive. When the difference is negative, then the population playing s_i decreases because its derivative is negative. It is not difficult to see that a Nash equilibrium p^* is a stationary point of the system of differential equations. This follows because if s_i is part of the support of p^* then $u_i(s_i, p^*) - u_i(p^*, p^*) = 0$ and if s_i is not part of the support then $p_i^* = 0$; in both cases, $dp_i(t)/dt = 0$ for all i .

Notice that stationary points are not necessarily Nash equilibria; any pure strategy is a stationary point for the replicator dynamics without mutation described above. Other selection processes exist and incorporate mutation into the differential (or difference) equations that govern the dynamics. The pertinent question is which equilibria of the game also have appealing dynamics properties. In this way, the evolutionary process refines the Nash equilibria. For example, if a totally mixed strategy of a finite, symmetric bimatrix game is a Lyapunov stable stationary state of the associated replicator dynamics, then it is also a Nash equilibrium. For additional information on evolutionary game theory, see Weibull [50].

This article has had two principal purposes. The first was to develop the idea of pure and mixed Nash equilibria for noncooperative strategic form games, including the analysis of canonical games (the Prisoners' Dilemma, Matching Pennies, and the Battle of the Sexes) to demonstrate the range of

possible equilibrium behavior. The second purpose was to summarize subsequent research regarding the number and computability of Nash equilibrium and attempts to refine Nash's equilibrium concept. Two comprehensive surveys on strategic equilibrium concepts are by Van Damme [55] and Hillas and Kohlberg [56]. These include discussions of the Nash equilibrium concept and mixed strategies. For a survey on bimatrix games, see Raghavan [57].

NETWORK RELIABILITY PERFORMANCE METRICS

SALVATORE D. ANTONIO

University of Naples
“Parthenope”, Naples, Italy

INTRODUCTION

This section illustrates the existing definitions for network performance and reliability metrics proposed by relevant standardization bodies such as IETF (Internet Engineering Task Force) or ITU-T. Two different definitions are provided by the two bodies for each metric, but it is worth noting that the different definitions of similar metrics are in most cases compatible, that is, semantically equivalent or easily convertible into one another. These metrics can be measured by using two alternative approaches: passive measurements and active measurements.

Active measurement techniques inject traffic into the network and evaluate traffic metrics by monitoring the injected traffic or the response to the injected traffic. Active test traffic may perturb other traffic already present on the network, the so-called background traffic; therefore, scheduling and volume of the injected traffic must be carefully configured.

Passive measurements provide information about traffic in the observed network by capturing all or a selected subset of the traffic flow packets traversing a monitoring point. Since no test traffic is generated, passive measurements can only be applied when the traffic of interest is already present on the network. The deployment of monitoring probes in the network can be performed in different ways, depending on the metrics of interest and on the communication technology; for example, via a physical line splitter, via a normal client connection in broadcast networks, or via a dedicated monitoring port on a switch or router.

NETWORK PERFORMANCE METRICS

One-Way Delay

Delay is used to measure the expected time for a network traffic packet to traverse the network from one host to another one.

IETF RFC 2679 [1] defines the one-way delay metric as the difference between the time when the destination host received the last bit of the test packet and the time when the source host sent the first bit of that packet.

RFC 2679 also distinguishes between a “singleton analytic metric” and a “sample.” The singleton is introduced to measure a single observation of one-way delay, while the sample is used to measure a sequence of singleton delays measured at times taken from a Poisson process. Based on these samples, several statistics are defined such as one-way-delay percentile, one-way-delay median, one-way-delay minimum, and one-way-delay inverse percentile.

If the test packet fails to arrive within a reasonable period of time, the one-way delay is taken to be undefined (informally, infinite).

The ITU-T document Y.1540 [2] defines the one-way delay metric as the time, $(t_2 - t_1)$ between the occurrence of two corresponding packet reference events, ingress event at time t_1 and egress event at time t_2 , where $(t_2 > t_1)$ and $(t_2 - t_1) \leq T_{\max}$. A packet transfer event occurs when the following conditions are met:

- packet crosses a measurement point;
- standard procedures applied to the packet verify that the header checksum is valid;
- the source and destination address fields within the packet header represent the addresses of the expected source host and destination host.

The two definitions from IETF and ITU-T for one-way delay can be considered compatible, as for both definitions the relevant events are (i) the time just before the packet is being put

on the wire and (ii) the time after complete reception of the packet at the destination.

To measure one-way metrics, synchronization of both transmission ends of the measurement device needs to be ensured. This synchronization may be done by GPS (global positioning system) clocks when the two ends are distant. When ends are colocated, synchronization may be done directly by the analyzer.

Round-Trip Delay

Round-trip delay is used to measure the expected time for network interaction between two hosts on a network; conceptually, it is equivalent to the sum of the two one-way delays, each experienced in one direction between two hosts.

Active measurement of round-trip delay as defined by the IETF in RFC 2681 [3] requires the observation of test packets transmitted in both directions between two endpoints across a network: a “source” host which sends the first packet and a “destination” host, which receives the first test packet and sends a test packet back to the source in reply. The round-trip delay is then calculated as the difference between the time at which the reply is received at the source and the time at which the original test packet was sent.

The procedure for passive measurement of round-trip delay is similar to that for active measurement: a packet is sent from a source to a destination, that packet causes the destination to send the packet back to the source, and the packets are identifiable at the source in order to correlate each packet of the round trip and calculate a delay. There are two potential architectures here: one utilizing a source observation point (OP) placed topologically close to the source of traffic, and one utilizing an additional destination OP placed topologically close to the destination of traffic.

Delay Variation

Delay variation is used to measure the variation in a sequence of delay values over time.

In RFC 3393 [4], the packet delay variation is presented as the difference between the one-way delays of two selected packets within a stream of packets across the

network paths. The definition relies on the introduction of a selection function F defining unambiguously the two packets from the stream selected for the metric.

Examples of a selection function are as follows:

- consecutive packets within the specified interval;
- packets with specified indices within the specified interval;
- packets with the minimum and maximum one-way delays within the specified interval;
- packets with specified indices from the set of all defined (i.e., noninfinite) one-way delay packets within the specified interval.

In Recommendation Y.1540, packet delay variation is defined based on the observations of corresponding packet arrivals at ingress and egress measurement points. More precisely, the end-to-end packet delay variation (v_k) for a packet k between a source host and a destination host is the difference between the absolute packet transfer delay (x_k) of the packet and a defined reference packet transfer delay, $d_{1,2}$, between the same measurement points: $v_k = x_k - d_{1,2}$.

The reference packet transfer delay, $d_{1,2}$, between the source host and the destination host can be the absolute packet transfer delay experienced by the first packet between the two measurement points or any other fixed packet delay.

Therefore, the delay variation of an individual packet is naturally defined as the difference between the actual delay experienced by that packet and a reference delay.

Recommendation Y.1540 also presents two alternative methods for summarizing the delay variation experienced by a population of packets:

A first method is to prespecify a delay variation interval and then observe the percentage of individual packet delay variations that fall inside and outside of that interval.

A second method consists of selecting upper and lower quantiles of the delay variation distribution and then measuring

the distance between those quantiles. It is suggested in Y.1540 to select the 99.9th percentile and then 0th percentile (i.e., the minimum), make measurements, and observe the difference between the delay variation values at these two quantiles for each interval.

Packet Loss

Packet loss denotes the expected probability that a transmitted packet will reach its destination and is usually expressed as a percentage. It is a general metric for a network's packet delivery reliability. The IETF and ITU-T approaches are generally compatible, given assumptions about the measurement methods in use.

RFC 2680 [5] defines the one-way packet loss metric as follows: the one-way packet loss of a packet from a source host to a destination host is 0 if the source host sent the first bit of the packet to the destination host at time T and the destination host received that packet. The one-way packet loss of a packet from a source host to a destination host is equal to 1 if the source host sent the first bit of the packet to the destination host at time T and the destination host did not receive that packet.

RFC 2680 also relates the definition of one-way packet loss to one-way delay. More precisely, it is stated that the one-way packet loss is equal to 0 exactly when the one-way delay assumes a finite value, whereas an infinite value of the one-way delay corresponds to a one-way packet loss equal to 1. Furthermore, the document outlines the need for the measurement methodology to include a way to distinguish between a packet loss and a very large, but finite, delay. As with delay measurements, the threshold time to consider a late packet lost should be reported as part of the measurement results.

Recommendation Y.1540 defines the packet loss ratio as the ratio of total lost packet outcomes to total transmitted packets in a population of interest.

One-way active packet loss measurements always include the sending of test packets from a sender to a packet receiver in a predefined sending schedule and/or pattern; the receiver will then count these packets.

Usually, the test packets contain a specific content including sequence numbers and timestamp so that analysis by the receiver can be more detailed.

Passive measurements of one-way packet loss are only possible through multipoint measurement, or by observing traffic from which packet loss can be deduced from higher layer header fields. In both cases, it is important to ensure that all of the packets of interest do pass the observation point(s). In the first approach, routers or measurement probes along the path of the traffic of interest are instructed to filter and count the packets. Periodically, the probes export counters per flow and differences along the path can be compared to compute and localize the packet loss.

The second approach is possible with a single point measurement, but only for protocols whose packet headers have certain fields allowing the deduction of skipped, lost, or retransmitted packets.

NETWORK RELIABILITY METRICS

Availability

In general, the availability of a system as a function of time, $A(t)$, can be defined as the probability that the system is operational at the instant of time, t . If the limit of this function exists as t goes to infinity, it expresses the expected fraction of time that the system is available to perform useful computations.

ITU-T defines the service availability metric in ITU-T Recommendation Y. 1540 [2]. Such metric relies on the notion of packet loss ratio, measured as a percentage of lost packets across an interval of time. If the packet loss percentage is below a certain defined level during this time interval, then the service is called available in this time slot, else it is unavailable. On the basis of the availability results (yes/no) for consecutive time intervals, the document defines the percentage of (un)availability as follows:

- *Percent Service Unavailability.* The percentage of total scheduled service time

that is categorized as unavailable using the service availability function.

- *Percent Service Availability.* The percentage of total scheduled service time that is classified as available using the service availability function: percent service availability = $100 - \text{percent service unavailability}$.

IETF defines the concept of connectivity as a measure of the expected probability that one host can reach another and then, as an attribute affecting the service availability. RFC 2678 [6] defines metrics which allow to define the level of connectivity between two hosts A_1 and A_2 . It starts with the definition of an analytic metric, called instantaneous unidirectional connectivity, to define one-way connectivity at one single moment in time. This metric is extended to introduce the concept of bidirectional connectivity (for one single moment in time), and later to connectivity within a certain period of time. Each of the mentioned metrics produces a Boolean value which states whether the desired level of connectivity has been achieved or not. A methodology for estimating the last defined metric is sketched in the document. This methodology consists in using randomly distributed start times for sending the probe packets within a selected interval of time. The document also shows how to apply this testing methodology for checking TCP-based connectivity.

Reliability

The reliability of a system as a function of time, $R(t)$, is the conditional probability that the system has survived the interval $[0, t]$, given that the system was operational at time $t = 0$.

Reliability in this context is used to describe systems in which repair cannot take place; for example, systems in which the computer is serving a critical function and cannot be lost even for the duration of a repair, or systems where the repair is prohibitively expensive.

The reliability function $R(t)$ holds the following properties:

- It is a monotonically decreasing function.
- $R(t = 0) = 1$ (the component is assumed to work correctly in the beginning).
- For $R(t = \text{TTF}) = 0$ (the component will eventually fail), where TTF is the time to failure.

Unreliability, Probability of Failure

Unreliability (also referred to as the probability of failure) $F(t)$, is a property related to reliability by this law:

$$R(t) + F(t) = 1$$

$F(t)$ is the cumulative distribution function (CDF) of the TTF random variable and represents the probability that the system fails in the time interval $[0, t]$. The parameter to be managed is the mean or expected value, the mean time between failure (MTBF).

Time to Repair

Time to repair (TTR) is the amount of time needed to restore system's correct service delivery after a failure has occurred. The parameter to be managed is the mean or expected value, the mean time to repair (MTTR). This metric represents the average time required to repair a failed component or device.

Maintainability and Maintenance

The maintainability CDF, $M(t)$, is defined as the probability of performing a successful repair action within a given time period. In other words, maintainability measures the ease and speed with which a system can be restored after a failure has occurred, or a maintenance plan may extend the lifetime of a system by interceding at a point before the TTF to replace components and thus, reset the TTF. For a maintenance plan to be effective, the time to maintain should be less than TTR (including any time to analyze the cause of a fault and to identify the required repair). If a system fails, a time variable may be introduced to measure the time needed to analyse the failure and repair the system.

Coverage

The coverage, c , is the parameter that measures the fault tolerance of a system. It is defined as the conditional probability that given the existence of a failure in the operational system, the system is able to recover and continue information processing with no permanent loss of essential information; that is, $c = P(\text{system recovers} \mid \text{system fails})$.

INTRODUCTION

A modern society may be viewed as a system of networks for transportation, communication, and distribution of energy, goods, and services. Network analysis can be used in the design, improvement, and rationalization of these subsystems. The origins of *graph theory* and *networks analysis* are old and diverse. In 1736, Leonhard Euler wrote the first article on a topic related to graph theory. The solution to the Königsberg's bridge problem considered in his article involves several basic concepts of graph theory. A succinct description of the problem follows.

One of the cities in Prussia was Königsberg. In this city there is an island called Kneiphof, surrounded by the river Pregel, as shown in Fig. 1. In this figure, A represents an island and B, C, and D represent land areas. The branches of the river are crossed by seven bridges a, b, c, d, e, f, and g. Is it possible to arrange a route such that each bridge is crossed exactly once? In 1736, at the age of 29, Euler modeled this problem using nodes to represent land areas and arcs to represent bridges. In his famous paper "The solution of a problem relating to the geometry of

position" (translated from German) [1], Euler demonstrated that this problem had no solution and indicated the required conditions for the solution to exist. Euler's procedure for solving the Königsberg bridge problem can be found in several bibliographical references, such as those by Biggs, Lloyd, and Wilson [2], Newman [3], and Scientific American [4].

The following milestones in the history of network analysis mark important developments since the beginning through the 1960s:

1. Euler, 1736: the Königsberg bridge problem
2. Kirchhoff, 1847: law of conservation of electrical current
3. Maxwell, 1864: electromagnetic theory applications
4. König, 1936: first book
5. Hitchcock, 1941: economic aspects of distribution problems
6. Koopmans, 1947: optimal utilization of transportation systems. This work marks a clear separation between network analysis and graph theory
7. Between 1950 and 1965: much emphasis was placed on the development of algorithms for linear networks
8. More recently: a strong effort has been concentrated on generalized networks, multicommodity networks, and nonlinear costs

In 1956, Orden [5] proposed a generalization of the transportation problem (TP) known as the *transshipment problem*. At approximately the same time, the maximum-flow problem and the minimum-cost flow problem were formulated and investigated by Ford and Fulkerson. From 1950 through 1965 much activity was directed toward developing *primal simplex methods* and *primal-dual methods*. The primal simplex specializations began with the work of Dantzig [6] and culminated with the paper by Johnson [7]. The primal-dual methods originated with Kuhn's Hungarian algorithm

Figure 1. Königsberg's seven bridges.

for the assignment problem (AP) [8], and culminated with the *out-of-kilter algorithm* by Fulkerson [9]. In 1975, the Royal Swedish Academy of Science awarded the Nobel Prize in Economic Science equally to Professor L. Kantorovich of the USSR and Professor T. C. Koopmans of the US. Both these individuals are associated with some of the first papers describing network-flow problems as we know them today.

Most of the work since the mid-1960s has involved the efficient implementation of basic techniques and their extension to (i) linear networks with arc flow gain/loss factors, (ii) linear multicommodity networks, (iii) linear networks with side constraints, and (iv) network problems with nonlinear convex cost functions. New methods invented in the 1980s challenged the old ones. Two of these methods originally proposed by Bertsekas are called *relaxation and auction* [10,11].

Network models have some distinct characteristics that have resulted in a remarkable growth in both industry and business applications. The following are perhaps the most important of these characteristics:

1. Ability to model complex systems
2. Mechanistic procedure
3. Identification of significant operation features
4. Data requirements
5. Starting point for further analysis

Furthermore, network-based solution procedures have some clear advantages over other more general models, including the following:

1. Accuracy
2. Acceptability

3. Computational efficiency
4. Effectiveness when used as components of optimization procedures

Network models have been successfully applied in a wide range of situations. Most of these models can be classified according to the following types of problems:

1. Warehousing and distribution
2. Project planning and scheduling
3. Equipment replacement
4. Cost control
5. Traffic studies
6. Transportation systems
7. Queueing analysis
8. Assembly line balancing
9. Inventory control
10. Manpower allocation (and many others)

Definitions, Notations, and Symbolism

A *node* is a point where flow is originated, relayed, or terminated. If the *net flow* (defined as flow out minus flow in) is strictly positive the node is a *source*, if it is equal to zero the node is an *intermediate node*, and if it is strictly negative the node is a *terminal*. An *arc* is a generic channel for transmission of flow from a given node to another one directly connected from it. The *orientation* of the arc is represented by an arrow connecting the start node to the end node of the arc. There are three types of arcs (also called branches): *undirected*, *directed*, and *bidirected*, depending on the specification of the direction along which flow can move along the arcs. An undirected arc has no direction, while a directed arc has a unique direction specified in advance. A bidirected arc actually has two directions specified in advance. To represent networks graphically, we use circles to indicate nodes, lines to indicate arcs, and arrowheads to indicate arc orientation. We also use the notation (i,j) to refer to the directed arc leading from node i to node j . Figure 2a shows an undirected arc, Fig. 2b a directed arc, and Fig. 2c a bidirected arc.

Figure 2. Node-arc representations: (a) undirected arc; (b) directed arc; (c) bidirected arc.

Figure 3. Representation of a bidirected arc by two directed arcs.

For most practical purposes, there is no necessity to distinguish between undirected and bidirected arcs. Further, it is evident that a bidirected arc between two arbitrary nodes i and j can be represented by two directed arcs (i, j) and (j, i) , as shown in Fig. 3.

If an arc is traversed by flow in the same direction of the orientation, the arc is said to be a *forward* arc. If it is traversed in a direction opposite to its orientation, the arc is said to be a *reverse* arc. When the flow along an arc is constant, the arc is referred to as a *pure* arc; otherwise, it is referred to as a *generalized* arc. Generalized arcs allow *gains* and *losses* on arc flows. In these arcs the flow at the end node is equal to the flow at the start node multiplied by a positive constant known as the gain/loss factor.

A *network* is a collection of nodes and arcs, with one or more quantitative elements associated with each arc or node. Networks can be *pure* or *generalized*, depending on the values of the gain/loss factors. A *graph* $G = (\mathbf{N}, \tau)$ is the pair consisting of a set $\mathbf{N}$ and function τ mapping $\mathbf{N}$ into $\mathbf{N}$. Whenever possible, the elements of set $\mathbf{N}$ will be represented by points in the plane and if x and y are two points such that $y \in \tau x$, then they will be joined by a continuous line with an arrow head pointing from x to y . Hence, an element of $\mathbf{N}$ is called a point or vertex or node of the graph while the pair (x, y) with $y \in \tau x$ is called an arc of the graph. The set of arcs of the graph is denoted by $\mathbf{A}$ and instead of $G = (\mathbf{N}, \tau)$ we can write $G = (\mathbf{N}, \mathbf{A})$. An illustration of a network is given in

Figure 4. Illustrative network.

Fig. 4. Nodes 1 and 2 are source nodes and nodes 6 and 7 are sink nodes. Here, $\mathbf{N} = \{1, 2, 3, 4, 5, 6, 7\}$. Also, $\tau_1 = \{3, 5\}$, $\tau_2 = \{4, 5\}$, $\tau_3 = \{4, 5, 6\}$, $\tau_4 = \{4, 5, 7\}$, $\tau_5 = \{3, 6, 7\}$, $\tau_6 = \tau_7 = \emptyset$. Therefore, $\mathbf{A} = \{(1, 3), (1, 5), (2, 4), (2, 5), \dots, (5, 7)\}$.

A *chain* is a connected sequence of all forward (or all reverse) arcs. An example of a chain is the sequence of nodes 1-2-3-4-5-6 in Fig. 5a. A *path* is a connected sequence of forward and reverse arcs. An example of a path is the sequence 1-4-3-6 in Fig. 5a. A *circuit* is a chain such that the first and last nodes coincide. An example of a circuit is the sequence 3-4-5-3 in Fig. 5a.

A *cycle* is a path such that the first and last nodes coincide. An example of a cycle is the sequence 2-3-4-2 in Fig. 5b. A *self-loop* is a one-arc cycle (circuit). An example of a self-loop is shown in Fig. 4 for node 4. Often in the network literature we can find that the terms *chain* and *circuit* are defined as we have defined the terms *path* and *cycle*, respectively, and vice versa.

As mentioned in the introduction of this article, in his article on the Königsberg bridge problem, Euler replaced the map shown in Fig. 1 by a graph in which nodes represent land areas and arcs represent bridges, as shown in Fig. 6. Using this figure, the

Figure 5. (a) Network with circuits; (b) network without circuits; (c) acyclic network.

Figure 6. Königsberg bridge problem graph.

object of the Königsberg bridge problem can be restated as finding a path that contains each arc of the graph exactly once. A path of this kind is now known as an *Eulerian path*.

A *connected* graph is one such that at least one path exists between every pair of nodes. A *tree* is a finite connected graph with no cycles and possessing at least two nodes. A *spanning tree* is a tree which contains *all* nodes of a given graph. A finite graph is an *arborescence* with root x if: (i) every node different from x is the terminal node of a single arc, (ii) x is not the terminal node of any arc, (iii) there are no circuits.

Figure 7a shows an undirected network, and Fig. 7b–c shows a spanning tree and a nonspanning tree, respectively, for that network. Figure 7d shows a directed network, and Fig. 7e–f shows an arborescence and an arborescent spanning tree, respectively, for the network. Figure 7g–h shows a tree and a spanning tree, respectively, for the network shown in Fig. 7d.

Other graph theory concepts (where the orientation of arcs is undirected) that may prove useful are the following. A *subgraph* of a graph $(\mathbf{N}, \mathbf{A})$ is a pair $(\mathbf{N}', \mathbf{A}')$ where $\mathbf{N}'$ is a subset of $\mathbf{N}$ and $\mathbf{A}'$ is a subset of

$\mathbf{A}$, where $(i, j) \in \mathbf{A}'$ only if both i and j are elements of $\mathbf{N}'$. A *clique* of a graph $(\mathbf{N}, \mathbf{A})$ is a subgraph $(\mathbf{N}', \mathbf{A}')$ where for all $i, j \in \mathbf{N}'$ we have $(i, j) \in \mathbf{A}'$. Furthermore, given a graph $(\mathbf{N}, \mathbf{A})$, a subgraph $(\mathbf{N}', \mathbf{A}')$ where every node of $\mathbf{N}'$ has exactly one arc of $\mathbf{A}'$ associated with it is called a *matching*. Finally, a graph is considered *bipartite* if it contains no odd cycles.

Matrix Representation of Networks

Let $G = (\mathbf{N}, \mathbf{A})$ be a directed network. The *adjacency matrix* summarizes the *connectivity* of the network by specifying which nodes are directly connected by arcs. It is defined as $\mathbf{X} = [x_{ij}]$, where $x_{ij} = 1$ if (i, j) exists, and 0 otherwise. The *node-arc-incidence matrix* also summarizes the connectivity of the network by specifying the position of each node with respect to the arcs of the set $\mathbf{A}$. It is defined as $\mathbf{Z} = [z_{ik}]$, where $z_{ik} = +1$ if node i is the starting node of arc a_k ; $z_{ik} = -1$ if node i is the ending node of arc a_k ; $z_{ik} = 0$, otherwise. As an illustration, the network shown in Fig. 8 is considered. For this network, $\mathbf{N} = \{1, 2, 3, 4, 5, 6\}$ and $\mathbf{A} = \{a_1, a_2, a_3, a_4, a_5, a_6, a_7, a_8, a_9\}$. Also, the adjacency matrix is shown below:

$$\mathbf{x} = \begin{bmatrix} 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

Again, for the network of Fig. 8, the node-arc-incidence matrix is shown below:

Figure 7. Trees and arborescences.

Figure 8. Directed network consisting of 6 nodes and 9 arcs.

$$\mathbf{z} = \begin{bmatrix} +1 & +1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 0 & +1 & 0 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & +1 & 0 & -1 & 0 & -1 & 0 \\ 0 & -1 & 0 & 0 & +1 & +1 & +1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & +1 & +1 \\ 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & -1 \end{bmatrix}$$

A network can be represented more effectively using two *connectivity lists*: (i) nodes at the beginning of directed arcs going into nodes $1, 2, 3, \dots, n$, (ii) number of directed arcs into nodes $1, 2, 3, \dots, n$. Alternatively, the first list shows nodes at the end of arcs coming from nodes $1, 2, 3, \dots, n$, and the second list indicates the number of arcs from each node. The information in the distance (or cost or capacity) matrix can be more efficiently stored in a third list when using connectivity lists. Consider again the network given in Fig. 8. This network can be represented in terms of two lists: (i) nodes at the beginning of directed arcs going into nodes $1, 2, 3, \dots, n$, (ii) number of directed arcs into nodes $1, 2, 3, \dots, n$. These two lists are shown below:

Figure 9. Network with arc lengths.

List 1:

-1	4	2	4	5	1	4	3	5
----	---	---	---	---	---	---	---	---

List 2:

0	2	3	1	1	2
---	---	---	---	---	---

The *cost* or *distance matrix* summarizes the natural limitations and capabilities of the network (system). Let $G = (\mathbf{N}, \mathbf{A})$ be a directed network. The *cost* or *distance matrix* is defined by $\mathbf{C} = [c_{ij}]$, where c_{ij} is the parameter associated with each arc (i, j) in $\mathbf{A}$. As an example, the network shown in Fig. 9 will be considered.

For this network the distance matrix $\mathbf{C}$ is given below:

$$\mathbf{C} = \begin{bmatrix} 0 & 2 & 5 & 16 \\ \infty & 0 & 2 & 3 \\ \infty & 2 & 0 & 10 \\ 5 & \infty & \infty & 0 \end{bmatrix}$$

The information in the distance (or cost or capacity) matrix can be more efficiently stored in a third list when using the *forward-star representation*. As an illustration, the connectivity and arc length information for the network shown in Fig. 9 can be represented as follows:

List 1:

4	1	3	1	2	1	2	3
---	---	---	---	---	---	---	---

List 2:

1	2	2	3
---	---	---	---

List 3:

5	2	2	5	2	16	3	10
---	---	---	---	---	----	---	----

Conservation of Flow

First we consider a pure network. Let s, t be source and terminal nodes, α_i the set of all directed arcs starting at node i , and β_i the set of all arcs ending at node i . Furthermore, let

c_{ij} be the capacity of (i, j) . Flow conservation at node i means that the net flow at this node is equal to zero. The flow conservation is formulated in Equation (1):

$$\sum_{j \in \alpha_i} f_{ij} - \sum_{j \in \beta_i} f_{ji} = 0 \quad i \neq s, t \quad (1)$$

where, for feasibility, the condition $0 \leq f_{ij} \leq c_{ij}$, must hold for all (i, j) .

In the case of a generalized network the flow conservation condition for node i is formulated as shown in Equation (2), where a_{ji} is the *gain/loss factor* of arc (j, i) :

$$\sum_{j \in \alpha_i} f_{ij} - \sum_{j \in \beta_i} a_{ji} f_{ji} = 0 \quad i \neq s, t \quad (2)$$

It can be easily verified that the coefficient matrix corresponding to the flow conservation constraints is the $\mathbf{Z}$ matrix (node-arc-incidence matrix). To illustrate this, the *pure* network shown in Fig. 10a will be considered.

The numbers associated with the arcs of the network in Figure 10a are the *gain/loss* factors, which by definition are all equal to 1. Figure 10b shows a *generalized* network with gain/loss factors given next to each arc. The coefficient matrix corresponding to the *pure* network given in Fig. 10a is

$$\begin{bmatrix} 1 & 1 & 0 & 0 & 0 & 0 \\ -1 & 0 & 1 & 1 & -1 & 0 \\ 0 & -1 & -1 & 0 & 1 & 1 \\ 0 & 0 & 0 & -1 & 0 & -1 \end{bmatrix}$$

Similarly, the coefficient matrix corresponding to the *generalized* network shown in Fig. 10b is

$$\begin{bmatrix} 1 & 1 & 0 & 0 & 0 & 0 \\ -3 & 0 & 1 & 1 & -1/4 & 0 \\ 0 & -6 & -2 & 0 & 1 & 1 \\ 0 & 0 & 0 & -2/3 & 0 & -1/3 \end{bmatrix}$$

If we now assume that node 1 has a supply of 5 units of flow and node 2 has a demand of one unit in the network shown in Fig. 10b, the flow at the end of path 1-3-2-4 is equal to $[5(6)(1/4) - 1](2/3) = 13/3$. Moreover, the flow conservation condition for node 3 is $f_{32} + f_{34} - 2f_{23} - 6f_{13} = 0$.

Figure 10. (a) Pure network; (b) Generalized network.

Cut and Cut Value

Let us for now consider a network with 0 lower bounds on arc flows. A *cut* is defined as a *set of arcs* whose removal will *not* allow any flow to be transmitted from a source s to a terminal t . As an illustration, in the network shown in Fig. 11, it is noted that a cut disconnecting node 1 from node 4 consists of arcs (1,3), (2,3), and (2,4). This cut has a capacity or value equal to 15.

More generally, the value of a cut between two nodes s and t on a directed pure network with *positive* lower bounds L_{ij} and upper bounds U_{ij} on arc flows is defined in Equation (3):

$$C = \sum_{i \in N_1} \sum_{j \in N_2} U_{ij} - \sum_{i \in N_1} \sum_{j \in N_2} L_{ji} \quad (3)$$

In the definition given in Equation (3), the set of nodes is partitioned into two sets N_1 and N_2 and, as illustrated in Fig. 12, such that $s \in N_1$ and $t \in N_2$.

Example. The definition of cut-set value given in Equation (3) will be illustrated using the network of Fig. 13, where each arc has two parameters $[L_{ij}, U_{ij}]$ such that $L_{ij} \leq f_{ij} \leq U_{ij}$.

Figure 12. Illustration of cut-set value.

As can be seen in this figure, the nodes are *partitioned* into two sets $N_1 = \{1, 2\}$ and $N_2 = \{3, 4, 5\}$. It is desired to verify that the cut shown is a minimum cut whose value is equal to the maximum flow from node $s = 1$ to node $t = 5$. For the given cut, according to Equation (3), the cut value is equal to

$$\sum_{i \in N_1} \sum_{j \in N_2} U_{ij} - \sum_{i \in N_1} \sum_{j \in N_2} L_{ji} = 5 + 4 - 4 = 5$$

Figure 11. A cut between nodes 1 and 4.

Figure 13. Minimum-cut illustration.

Figure 14. Maximum-flow illustrations.

By inspection, it is possible to determine that the maximum flow is equal to 5. Therefore, the cut shown in Fig. 13 is a minimum cut. The corresponding arc flows resulting in a maximum flow of 5 being delivered to node 5 are shown in Fig. 14a. Note that for the feasibility of the maximum flow, node 2 can be a terminal node with a demand equal to 2. Indeed, node 2 can be viewed as a terminal node with a flow demand equal to at least 2 and at most 66.

To further illustrate the concept under study, let us assume that instead of arc (4,3) in Fig. 13 we have arc (3,4) with parameters [11,12]. In this case, the minimum cut is still the same as in Fig. 13, and the arc flows are as in Fig. 14b. However, for the feasibility of the maximum flow it is necessary to make further assumptions. Specifically, node 3 becomes a source with supply equal to 4 and node 4 becomes a terminal with demand equal to 4, as shown in Fig. 14b. There are other illustrations resulting in the same values for the minimum cut and the maximum flow in Fig. 14.

DETERMINISTIC NETWORK MODELS

This section presents two fundamentally important flow models and several applications of these models. The summary presented here is based on the work by Phillips and Garcia-Diaz [13]. The network models are well known as the Maximum-Flow Model and the Minimum-Cost Model. They will be presented in the section titled "Maximum-Flow and Minimum-Cost Flow Models". The applications are summarized in the section titled "Applications of Network Models".

Maximum-Flow and Minimum-Cost Flow Models

Maximum-Flow Model. Let $G = (\mathbf{N}, \mathbf{A})$ be directed and capacitated, $\mathbf{N} = \{1, 2, \dots, n\}$. Source is node 1; terminal is node n . Also, U_{ij} is the capacity of arc (i, j) and it is assumed that there is an infinite availability of flow at the source node. It is desired to find the

maximum flow shipped from 1 to n through the arcs in $\mathbf{A}$. Let f_{ij} be the flow from i to j along arc (i,j) , and let V be the amount of flow into the terminal (or out of the source). As before, α_i is the set of all directed arcs starting at node i , and β_i is the set of all arcs ending at node i . The linear programming (LP) formulation for this problem is given by Equations (4)–(6):

$$\begin{aligned} & \text{Maximize } V \\ & \text{subject to} \end{aligned} \quad (4)$$

$$\sum_{j \in \alpha_i} f_{ij} - \sum_{j \in \beta_i} f_{ji} = \begin{cases} V & i = 1 \\ 0 & i \neq 1, n \\ -V & i = n \end{cases} \quad (5)$$

$$0 \leq f_{ij} \leq U_{ij} \quad (i,j) \in \mathbf{A} \quad (6)$$

Minimum-Cost Flow Model. Let $G = (\mathbf{N}, \mathbf{A})$ be directed and capacitated. As before, α_i is the set of all directed arcs starting at node i , and β_i is the set of all arcs ending at node i . Let b_i be the flow supply at node i . Let c_{ij} be the per-unit cost of flow along (i,j) . Also, let L_{ij} be a lower bound on the flow on arc (i,j) . The model is shown in Equations (7)–(9):

$$\text{Minimize } \sum_{(i,j) \in \mathbf{A}} c_{ij} f_{ij} \quad (7)$$

subject to

$$\sum_{j \in \alpha_i} f_{ij} - \sum_{j \in \beta_i} f_{ji} = b_i \quad i \in \mathbf{N} \quad (8)$$

$$L_{ij} \leq f_{ij} \leq U_{ij} \quad (i,j) \in \mathbf{A} \quad (9)$$

where b_i is positive for source nodes, zero for intermediate (transshipment) nodes, and negative for terminal nodes.

Maximum-Flow Minimum-Cut Theorem. A *minimum cut* is one having minimum-cut value among all possible cuts between nodes s and t . The *Maximum-Flow Minimum-Cut Theorem* [14] specifies that the *maximum* flow from s to t is equal to the capacity of the *minimum* cut between s and t . As an illustration of this result, it can be verified that the maximum flow that can be shipped from node s to node t in the network of Fig. 15 is

Figure 15. Minimum cut for a directed network.

Figure 16. Minimum-cut for an undirected network.

equal to 3. In this figure, the numbers shown on the arcs are the corresponding flow capacities in the specified directions. The minimum cut consists of arcs (1,2) and (3,4), and has a capacity equal to 3 units.

Finally, if the network is undirected, the maximum flow from node s to node t would be equal to 4, since the minimum cut in this case consists of arcs (1,2), (2,3), and (3,4), as shown in Fig. 16.

Minimum-Cost Flow Model for Generalized Networks. At this time we want to emphasize the difference between pure and generalized networks. The network whose formulation is shown in Equations (7)–(9) is referred to as a *pure* network because of the constancy of its flow along the arcs. In many applications, however, the flow entering an arc is not equal to the flow exiting the same arc. This flow may actually be equal to the initial flow multiplied by a positive constant known as the *gain/loss factor*. When the multiplier is larger than 1 it is called a gain factor; otherwise, it is called a loss factor.

Let $G = (\mathbf{N}, \mathbf{A})$ be a directed and capacitated generalized network. The flow entering arc (i,j) is represented by f_{ij} and the

gain/loss factor for this arc is represented by a_{ij} . Furthermore, let c_{ij} , L_{ij} and U_{ij} be the per-unit cost, lower bound, and upper bound, respectively, for the initial flow on arc (i, j) . Also, let b_i be the net flow supply at node i . As before, α_i is the set of all directed arcs starting at node i , and β_i is the set of all arcs ending at node i . The model shown in Equations (7)–(9) can be reformulated as in Equations (10)–(12).

$$\text{Minimize } \sum_{(i,j) \in \mathbf{A}} c_{ij} f_{ij} \quad (10)$$

subject to

$$\sum_{j \in \alpha_i} f_{ij} - \sum_{j \in \beta_i} a_{ji} f_{ji} = b_i \quad i \in \mathbf{N} \quad (11)$$

$$L_{ij} \leq f_{ij} \leq U_{ij} \quad (i, j) \in \mathbf{A} \quad (12)$$

where b_i is positive for source nodes, 0 for intermediate (transshipment) nodes, and negative for terminal nodes.

Applications of Network Models

The applications presented in this section can be classified into two broad categories. The first category includes applications where the solution to a problem is achieved by selecting a chain or cycle that optimizes a suitable objective function. In these problems each arc is interpreted as a directed link that allows the movement of one unit of flow from the start node to the end node of the arc. The arc parameter or *length* is a generic cost of using the arc. Usually, these models are referred to as *distance networks*. In the second category, a more general interpretation of an arc is used, namely, that of a device or channel used for shipping multiple units of flow. In this case, the arc parameter represents the maximum amount of flow per unit time that can be shipped along the arc at any time. This parameter is called the *capacity* of the arc, and the network models are referred to as *capacitated flow networks*.

Equipment Replacement.

Problem Definition. It is desired to find an optimal machine replacement policy for an n -year planning horizon under the assumption

Figure 17. Equipment replacement network.

that the machine can be replaced instead of repaired at the beginning of each year.

Network Representation. Nodes represent beginning of periods (years); arcs represent periods of useful service life (replacement alternatives); arc parameters represent costs of replacement alternatives. This cost is equal to replacement cost plus operating cost minus salvage value. The network consists of $n + 1$ nodes. A chain from $s = 1$ to $t = n + 1$ represents a replacement policy.

As an illustration, we consider a planning period of $n = 3$ years. Here $s = 1$ and $t = 4$. The optimal solution is given by the shortest *chain* from node 1 to node 4. The set of all replacement plans can be represented by the chains in the network in Fig. 17. For example, the chain $(1,3) - (3,4)$ represents the policy of buying a machine at the beginning of period 1, keeping it for 2 years and selling it at the end of period 2 (beginning of period 3). A new machine is then purchased at the beginning of period 3 and sold at the end of the same period. The total cost of this policy is $c_{13} + c_{34}$.

Network Solution. The optimal solution corresponds to the shortest *chain* from node 1 to node t . In the absence of *negative* circuits (one with total length being negative), the shortest chain can be easily found using Dijkstra's algorithm [13].

Project Planning.

Problem Definition. A project is defined as a collection of activities and events. An activity is any undertaking that consumes time and other resources. An event is a well-defined occurrence in time. An *Activity Network* is a representation of two particular aspects of a project: (i) precedence

Figure 18. Activity-on node network.

Figure 19. Activity-on arc network.

relationships among the activities, (ii) duration of each activity. The precedence relationships come about from technological and other considerations. The precedence relationships are transitive, nonreflexive, and nonsymmetric.

Network Representation. Let $G(\mathbf{N}, \mathbf{A})$ be an activity network satisfying three conditions: (i) one source, (ii) one terminal, and (iii) at most one arc to directly connect two nodes. There are two representations: **A-on-N** (Activity-on Node) and **A-on-A** (Activity-on Arc). These are illustrated in Figs 18 and 19 for a case involving five activities. In Fig. 19 the dashed line represents a *dummy* activity (duration equal to 0) created in order to avoid both arcs 1 and 2 joining exactly the same two nodes.

Network Solution. For a *node* to be *realized*, all *arcs* ending at the node must be *completed*. Additionally, for an arc to be *started* its *beginning node* must be realized. Under these rules, it can be verified that the *critical* activities and events (those that would delay the project if they are delayed themselves) correspond to the *longest* path from the source to the terminal of the network. In this case finding the longest path is straightforward because the network is *circuitless*. When the network has *positive* circuits (one with total length being positive), the longest path problem becomes very hard to solve.

The Caterer Problem.

Problem Definition. A caterer knows that he will require d_j clean napkins on each of n successive days, $j = 1, 2, \dots, n$. He can meet his needs by purchasing new napkins and by using napkins previously laundered. The laundry has two kinds of service, quick and slow. A napkin sent for slow service is available 2 days later, whereas a napkin sent to the fast service is available 1 day later. New napkins from the store cost a cents each, quick laundry service is c cents per napkin, and slow service b cents per napkin, $b < c$. How does the caterer meet his requirements at minimum cost?

Linear Programming Model: Case 1. Let p_j, s_j, q_j , and h_j be the number of napkins purchased, sent to slow service, sent to quick service, and held over on day j , respectively. The LP model for $n = 3$ is shown in Equations (13)–(16).

$$\text{Minimize } \sum_{j=1}^3 (ap_j + cq_j + bs_j) \quad (13)$$

subject to

$$p_j + s_{j-2} + q_{j-1} \geq d_j \quad j = 1, 2, 3$$

$$\text{(demand for clean napkins)} \quad (14)$$

$$s_j + q_j + h_j - h_{j-1} \leq d_j \quad j = 1, 2, 3$$

$$\text{(supply of soiled napkins)} \quad (15)$$

$$h_j, p_j, s_j, q_j \geq 0 \quad j = 1, 2, 3 \quad (16)$$

Revised Linear Programming Model: Case 2. This revision is done to allow excess purchasing of new napkins. The LP formulation is shown in Equations (17)–(20).

$$\text{Minimize } \sum_{j=1}^3 (ap_j + cq_j + bs_j) \quad (17)$$

subject to

$$p_j + s_{j-2} + q_{j-1} + E_{j-1} - E_j \geq d_j \quad j = 1, 2, 3$$

(demand for clean napkins) (18)

$$s_j + q_j + h_j - h_{j-1} \leq d_j \quad j = 1, 2, 3$$

(supply of soiled napkins) (19)

$$h_j, p_j, s_j, q_j \geq 0 \quad j = 1, 2, 3$$

(20)

Network Representation. Let us consider Case 1 again, assuming that $a_j = a, c_j = c$, and $b_j = b$, for the appropriate values of the index j . Furthermore, let $d_1 = 10, d_2 = 20$, and $d_3 = 5$. In the model shown below, the first three constraints are for clean napkins. The next three constraints are for dirty napkins. In these constraints the net flow is defined as flow out minus flow in. Moreover, the net flow is negative for terminal nodes and positive for source nodes. The seventh constraint is for network circulation, and the last one represents the nonnegativity condition for arc flows.

$$\begin{aligned} \text{Minimize } & a(p_1 + p_2 + p_3) + c(q_1 + q_2) + bs_1 \\ \text{subject to } & -p_1 = -10 \\ & -p_2 - q_1 = -20 \\ & -p_3 - q_2 - s_1 = -5 \\ & s_1 + q_1 + h_1 = 10 \\ & q_2 + h_2 - h_1 = 20 \\ & h_3 - h_2 = 5 \\ & p_1 + p_2 + p_3 - h_3 = 0 \\ & p_1, p_2, p_3, q_1, q_2, s_1, h_1, h_2, h_3 \geq 0 \end{aligned}$$

A network for Case 1 with $n = 3$ is given in Fig. 20, where the variables are indicated adjacent to their respective arcs and the supplies (positive values) and demands (negative values) are given adjacent to the nodes. The unique aspect of this problem is that the demand for clean napkins d_j also works as a supply of dirty napkins at the end of each period.

The corresponding *circulation networks* (a network with only *intermediate* nodes) for

Figure 20. Network for sample caterer problem.

Case 1 and Case 2 are shown in Fig. 21a and b.

In Fig. 21 each arc has a triplet of values $[U_{ij}, L_{ij}, c_{ij}]$. These symbols represent the upper bound on flow, the lower bound on flow, and the per-unit flow cost, respectively. The return arc $(3, s)$ is used to make sure that the total number of soiled napkins at the end of the planning period is equal to the total number of purchased napkins. All arcs not yet considered, should have triplets of values $[\infty, 0, 0]$ assigned to them.

Network Solution. The optimal solution corresponds to the flow resulting in minimum cost. As indicated before, the demand for clean napkins works as a supply of dirty napkins at the end of each period. To accomplish this, each arc in Fig. 21a directed from node j in the column of clean napkins to node j in the column of used napkins has *both* its lower and upper bounds set equal to d_j . Additionally, the per-unit flow cost is set equal to zero. Note that the given network does not allow holding new napkins for future days. Case 2 is a reformulation that allows this to happen by including the arcs in Fig. 21b corresponding to vertical arrows in the column of new napkins.

Employment Scheduling.

Problem Definition. A contract maintenance firm provides and supervises semiskilled manpower for major overhauls of chemical processing equipment. A standard job frequently requires a thousand or more men and may extend from 1 week to a few months.

Figure 21. Circulation networks for caterer problem.

Usually, the plant site is not located in a major metropolitan area, so workmen must be transported for several miles. The total labor expenses can be classified as follows: (i) operating expenses = transportation + food + housing + wages; (ii) cost not depending on how long the crew remains on site = recruiting + briefing + transportation. The demand for labor is deterministic but not necessarily uniform.

LP Formulation. Consider a planning horizon consisting of periods $1, 2, \dots, n-1$; let us use the following notation: x_{ij} = number of employees beginning employment at the start of period i and terminated at the start of period j ($1 \leq i \leq j \leq n$), c_{ij} = total cost per employee associated with x_{ij} , D_j = demand for labor in period j , S_j = excess not used in period j . The corresponding *min-cost formulation* is shown in Equations (21)–(24).

$$\text{Minimize } \sum_{r=1}^{n-1} \sum_{t=r+1}^n c_{rt} x_{rt} \quad (21)$$

subject to

$$\sum_{r=1}^j \sum_{t=j+1}^n x_{rt} - S_j = D_j \quad j = 1, 2, \dots, n-1 \quad (22)$$

$$S_j \geq 0 \quad j = 1, 2, \dots, n-1 \quad (23)$$

$$x_{ij} \geq 0 \quad 1 \leq i \leq j \leq n \quad (24)$$

In the above LP formulation, the double summation of constraint (22) represents the number hired by the beginning of period j and terminated after the beginning of period $j+1$.

Network Representation. This problem does not have an obvious network interpretation and it is only after some manipulation of the mathematical model that the network representation becomes evident. The procedure will be illustrated with the following example for $n = 4$. The corresponding constraints are given below:

$$\begin{array}{rcl} x_{12} + x_{13} + x_{14} & -s_1 & = D_1 \\ x_{13} + x_{14} + x_{23} + x_{24} & -s_2 & = D_2 \\ x_{14} & + x_{24} + x_{34} & -s_3 = D_3 \end{array}$$

By subtracting the first equation from the second one, the second equation from the third one and multiplying the third equation by -1 , we obtain

$$\begin{array}{rcl} x_{12} + x_{13} + x_{14} & -s_1 & = D_1 \\ -x_{12} & + x_{23} + x_{24} & + s_1 - s_2 = D_2 - D_1 \\ -x_{13} & -x_{23} & + x_{34} + s_2 - s_3 = D_3 - D_2 \\ -x_{14} & -x_{24} - x_{34} & + s_3 = -D_3. \end{array}$$

An examination of this set of equations reveals that each variable appears exactly twice in the equations, once with a $+1$ coefficient and once with a -1 coefficient. The network for this example is given in Fig. 22a, where the variables are shown next to the arcs and the supplies are shown next to the nodes. In this figure, nodes represent

Figure 22. (a) Employment scheduling network. (b) Illustration of employment scheduling network.

Table 1. Interpretation of Network Flows in Fig. 22b

Start of Period	Hired	Terminated	Excess	Working 1 Period	Working 2 Periods	Working 3 Periods	Available
1	13	0	3	4	4	5	13
2	7	4	4	2	5	—	16
3	2	6	7	2	—	—	12
4	—	12	—	—	—	—	—

the beginning of each period. Arcs correspond to all possible employment strategies. Any arc (i, j) such that $j > i$ is used to model the number of workers hired at the beginning of period i and terminated at the beginning of period j . Additionally, any arc (j, i) such that $i < j$ is used to model the excess personnel at the beginning of period i . The parameters for the complete formulation of the problem are node demands and arc costs. The optimal solution corresponds to the *minimum-cost flow* on the network.

An illustration of the model being discussed is considered now. Assume that $D_1 = 10, D_2 = 12, D_3 = 5$. A network with *feasible* flows for the above demand conditions is shown in Fig. 22b. The corresponding

interpretation of flows is summarized in Table 1.

Fleet Allocation

Problem Definition. A problem that often arises is the scheduling and routing of vehicles to accomplish the shipment of some commodity from points of supply to points of demand. There are two important versions of this problem. In Case 1 it is desired to maximize total profit. Case 2 focuses on the minimization of the fleet size. This can be accomplished by minimizing the number of idle ship days. In both cases it is desired to accomplish the stated objective under

the constraints that shipments must be delivered by their due dates.

Network Representation. A timescale is placed below the network. In addition to representing a source and a terminal, nodes represent port/date combinations. One node is defined for each date and place a shipment is delivered, and for each time and place a ship starts loading. Arcs indicate all possible trips with and without cargo. All arcs emanating from the source correspond to the first use of a ship. Additionally, all arcs ending at the terminal represent the removing of ships from service. For Case 1, the numbers shown next to each arc are costs per unit of flow (a unit of flow represents one ship). It is noted that profits are considered here as negative costs. All arcs have infinite flow capacities except those arcs representing shipments, which have capacities equal to 1. In the example shown in Fig. 23 these arcs having unit capacities are (A,C) with A at time 0, (A,C) with A at time 5, (B,D) with B at time 0, and (B,C) with B at time 4. Each chain from the source node to the terminal node represents a feasible schedule for a ship.

Network Solution. The optimal solution corresponds to the distribution of flow (number of ships used) having minimal cost. If a fleet of size M is used, the minimum-cost flow with a total of M units of flow will give the optimal ship schedules and also determine which shipments should be carried. If the fleet size is to be selected to maximize profit (Case 1), the problem can be solved parametrically (setting $M = 1, 2, \dots$) to determine the profit profile as the number of ships increased. For Case 2 the notation used is as follows:

- c_{ij} number of *idle ship days* associated with arc (i,j)
- f_{ij} flow (ships) on arc (i,j)
- L_{ij} minimum number of ships on arc $(i,j) = 1$ for *shipment arcs* and 0 otherwise
- U_{ij} maximum number of ships on arc $(i,j) = 1$ for *shipment arcs* and ∞ otherwise

A convenient way to represent Case 1 and Case 2 is using a *circulation network* with a *return arc* connecting the *terminal* to the

Figure 23. Fleet allocation network.

Figure 24. Fuel allocation network.

source. In Case 1, the lower and upper bounds on flow on the return arc are both equal to M and the cost per unit of flow is 0; alternatively, for Case 2, the lower bound is 0 and the upper bound is set equal to ∞ , with per-unit flow cost equal to ∞ .

Aircraft Fuel Allocation.

Problem Definition. Given the route of a single aircraft, it is desired to find the minimum-cost fuel purchasing policy under the existence of price differentials among the cities in the route, as well as burn-off penalties associated with excess (beyond minimum requirements) fuel carried on the aircraft. It is also assumed that fuel availability conditions for the cities, and fuel requirements for the flights are known.

Network Representation. The fundamental difference between this model and the previous model is that the fuel not used is subject to a reduction.

Nodes

Cities

Flights between cities

Arcs

Buying fuel in each city

Carrying fuel in aircraft

Using fuel for flight requirements

Carrying excess fuel after flights

Parameters

Minimum flow

Maximum flow

Per-unit flow cost

Burn-off penalty factor

Figure 24 shows a network for a four-city route. Node 1 is the source node. The intermediate nodes represent cities and flights between cities. Nodes 2, 3, 4, and 5 represent the four cities A, B, C, and D, respectively. Node 6 represents the flight from city A to city B. Node 7 represents the flight from city B to city C. Node 8 represents the flight from city C to city D. Node 9 represents the flight from city D to city A. Node 10 is the terminal node. Furthermore, the arcs are classified into four categories: (i) arcs coming out of the source represent buying fuel in each city, (ii) arcs (2,6), (3,7), (4,8), and (5,9) represent carrying fuel in the aircraft, (iii) arcs (6,3), (7,4), and (8,5) represent carrying excess fuel after flights, (iv) arcs into the terminal represent the use of fuel for flight requirements.

The arc parameters for any arc are: minimum flow, maximum flow, per-unit flow cost, and the burn-off penalty factor. These parameters can be listed for arc (i,j) as $[L_{ij}, U_{ij}, c_{ij}, A_{ij}]$. The arcs associated with excess fuel left at the end of a flight are generalized because of the burn-off losses. The arcs representing the fuel carried in the aircraft tank can be eliminated, if desired, since the fuel in the tank can be calculated by subtracting the amount used from the total available before a flight. An illustration of the model shown in Fig. 24 follows. Table 2 summarizes the data for this example.

Network Solution. This problem can be formulated as a *generalized minimum-cost*

Table 2. Fuel Allocation Example

Purchasing Strategies	Fuel Carrying Strategies	Excess Fuel Strategies	Requirements Strategies
(1,2) [0,1500,0.48,1]	(2,6) [0,2000,0,1]	(6,3) [0,2000,0,0.93]	(6,10) [1134,1134,0,1]
(1,3) [0,1000,0.49,1]	(3,7) [0,2000,0,1]	(7,4) [0,2000,0,0.96]	(7,10) [642,642,0,1]

(1,5) [0,1000,0.75,1]	(5,9) [0,2000,0,1]	—	(9,10) [910,910,0,1]

Figure 25. Optimal flows for fuel allocation network.

network problem whose LP model was shown in Equations (10)–(12). In this generalized network with losses, flow arriving at the end of an arc is less than the flow entering at the beginning of an arc. This class of network lends itself to a simplified and powerful representation of the *burn-off* penalties associated with excess fuel carried on an aircraft.

The optimal flows for the numerical example are shown in Fig. 25. The total cost of the fuel purchasing policy shown is \$1704.8. More details on this application are available in the article by Garcia-Diaz [15].

LINEAR PROGRAMMING AND NETWORKS

Totally Unimodular Matrix

A *unimodular* matrix is a square, integer matrix with determinant equal to 0, +1, or −1. An integer matrix (not necessarily square) is *totally unimodular* if every square, nonsingular submatrix of it is unimodular. The following statements are equivalent:

1. $\mathbf{A}$ is totally unimodular
2. $\mathbf{A}^T$ is totally unimodular
3. $(\mathbf{A}, \mathbf{I})$ is totally unimodular
4. A matrix obtained by deleting a row or column of $\mathbf{A}$ is totally unimodular

5. A matrix obtained by multiplying a row or column of $\mathbf{A}$ by -1 is totally unimodular
6. A matrix obtained by interchanging two rows or two columns of $\mathbf{A}$ is totally unimodular
7. A matrix obtained by duplicating rows or columns of $\mathbf{A}$ is totally unimodular
8. A matrix obtained by a *pivot operation* on $\mathbf{A}$ is totally unimodular.

A pivot operation is exactly the same operation in the Gaussian elimination technique resulting in a *column* with an entry equal to 1 in the position of the pivot and all other entries equal to 0.

Fundamental Results

The following theorems are stated without proof:

Theorem 1. If a matrix $\mathbf{D}$ is totally unimodular, then every basic solution of $\mathbf{D}\mathbf{f} = \mathbf{b}$, $\mathbf{f} \geq \mathbf{0}$, where $\mathbf{b}$ is an integer vector, is integer.

Theorem 2. $\mathbf{D}$ is totally unimodular if and only if $\mathbf{D}\mathbf{f} \leq \mathbf{b}$, $\mathbf{f} \geq \mathbf{0}$, where $\mathbf{b}$ is an integer vector, has all basic solutions integer.

Figure 26. Network models as special cases of LP model.

Theorem 3 [12]. An integer matrix $\mathbf{A} = [a_{ij}]$ with $a_{ij} = 0, 1, -1$, for all i and all j , is totally unimodular if: (i) No more than two nonzero elements appear in each column. (ii) The rows can be partitioned into two sets $\mathbf{E}_1$ and $\mathbf{E}_2$ such that (a) if a column contains two nonzero values with the same sign, one value is in each of the sets; (b) if a column contains two nonzero elements of opposite sign, both elements are in the same set.

The pure minimum-cost flow model formulated in Equations (7)–(9) can be reformulated using matrix notation as minimizing $\mathbf{Cf}$ subject to $\mathbf{Df} \leq \mathbf{b}$ and $\mathbf{f} \geq \mathbf{0}$, where $\mathbf{b}$ is an integer vector and $\mathbf{D}$ consists of matrices $\mathbf{Z}$ and $\mathbf{I}$. Since $\mathbf{Z}$ is totally unimodular (by Theorem 3), then $\mathbf{D}$ is totally unimodular. For this reason, optimal flows are integer when $\mathbf{b}$ is integer. However, in the case of a generalized network, the LP model formulated in Equations (10)–(12) does not generally satisfy the total unimodularity condition. Therefore, flows are no longer guaranteed to be integer even when the right-hand sides of the constraints are integer.

Special Cases

Now we focus on several well-known network problems that can be formulated as special cases of the model formulated in Equations (7)–(9). The problems are known as follows:

1. Transportation Problem (TP)
2. Assignment Problem (AP)
3. Maximum-Flow Problem (MFP)
4. Shortest-Path Problem (SPP)

Figure 26 illustrates the relationships among these problems. In this figure the problem mentioned at the *beginning* of an arrow is a *special case* of the problem shown at the *end* of the same arrow.

INTRODUCTION

The process of studying real-life complex systems often deals with large data sets arising in diverse applications including government and military systems, telecommunications, biotechnology, medicine, finance, astrophysics, ecology, geographical information systems, etc. [1,2]. Understanding the structural properties of a certain data set is in many cases the task of crucial importance. To extract useful information from the data, one often needs to apply advanced mathematical modeling techniques to summarize, visualize, and process the information contained in a data set. *Data mining* problems deal with multiple aspects of information retrieval from data sets, and a variety of techniques has been developed to address different types of tasks arising in this area [3].

During the past several years, *operations research (OR)* / *mathematical programming approaches* have received increased attention in the context of data mining problems [4]. Along with classical data mining techniques (e.g., support vector machines, artificial neural networks, decision trees, and K-means/K-median clustering), many recent studies deal with *network (graph)-based representations* of large real-world data sets and utilize graph-theoretic and network optimization concepts to extract useful and nontrivial information from these data sets. In this approach, a data set is represented

as a *graph (network)* with certain attributes associated with its vertices and edges.

Studying the structure of a graph representing a data set is often important for understanding the internal properties of the application it represents, as well as for improving storage organization and information retrieval. One can visualize a graph as a set of dots and links connecting them, which often makes this representation convenient and easily understandable.

The main concepts of graph theory were founded several centuries ago, and many network optimization algorithms have been developed since then. However, the trend of applying graph models to represent various real-life massive data sets has started relatively recently. Graph theory and related OR techniques are quickly becoming a field with a strong practical impact. The expansion of graph-theoretical approaches in various applications gave birth to the terms *graph practice* and *graph engineering* [5]. Graph (network)-based data mining techniques have gained significant popularity in recent years. Various aspects of this emerging field are addressed in Cook and Holder [6] and Washio and Motoda [7]. The term *network science* referring to a broad variety of network-based modeling approaches has also been widely used recently. In Alderson [8], the potential relevance between “network science” and OR is discussed. Although potential applications of OR in this broad field can be diverse, network-based data mining is among the areas where OR-based techniques can provide valuable contributions.

Network-based models allow one to extract information from real-world data sets using various standard concepts from graph theory. In many cases, one can investigate specific properties of a data set by detecting special formations in the corresponding graph, for instance, *connected components*, *spanning trees*, *cliques*, and *independent sets*. In particular, cliques and independent sets can be used for solving the important *clustering* problem arising in data mining,

which essentially represents partitioning the set of elements of a certain data set into a number of subsets (clusters) of objects according to some *similarity* (or *dissimilarity*) criterion. These concepts are associated with a number of network optimization problems that are discussed below.

Another aspect of investigating network models of real-world data sets is studying the global organization and structural properties of these networks, which are reflected by *degree distributions* of the constructed graphs. The degree distribution represents the large-scale pattern of connections in the graph, which reflects the global properties of the data set. One of the important results discovered during the last several years is the observation that many graphs representing the data sets from diverse areas (Internet, telecommunications, biology, and sociology) obey the *power-law* model [9,45]. The fact that graphs representing completely different data sets have a similar well-defined power-law structure has been widely reflected in the literature [2,5,10–13]. It indicates that global organization and evolution of data sets arising in various spheres of life follow similar laws and patterns. This fact served as a motivation to introduce the concept of “self-organized networks.” The information about the degree distribution of a graph that represents a certain data set can be significant in the data mining context, since it may allow one to analytically predict the size of certain types of clusters in this graph (e.g., connected components, cliques, and other structures). In particular, the size of connected components (clusters) in very large power-law graphs has been studied in Aiello *et al.* [9].

Further in this article, we address the main issues and concepts arising in network-based data mining. Specifically, we will describe the process of representing a data set as a graph using appropriate similarity (proximity) measures, which serves as a basis for applying graph-theoretic and network optimization techniques. These concepts and techniques are discussed later in the article. Finally, we give several examples of popular application areas of network-based data mining.

SIMILARITY MEASURES USED IN GRAPH-BASED DATA MINING

As indicated above, the essence of network-based data mining is representing a data set under consideration as a network (graph) where vertices and edges are constructed according to certain principles that may depend on the structure and origin of the data set. The vertices of the graph usually represent data records (objects), whereas the edges that connect the vertices are constructed using an appropriate *similarity criterion*. That is, two data objects (vertices) are connected if they are “similar enough” to each other. However, there are a lot of different ways to quantify the degree of similarity. In this section, we specifically address possible types of *similarity measures* (also referred to as *proximity measures*) between data objects that can be used for constructing the corresponding graph representations of data sets.

In a standard setup of many data mining problems, one deals with a data set of N data records that can be represented by vectors $x^i = (x_1^i, x_2^i, \dots, x_n^i)$, $i = 1, \dots, N$, where every vector x^i has n components that are referred to as the *features*, or *attributes*, of the data record. The similarity measure between any two data records would be defined by the corresponding values of their attributes. The following similarity measures are commonly used in practice.

- *Distance Metrics.* These can generally be expressed in the form

$$d(x, y) = \left(\sum_{j=k}^n |x_k - y_k|^r \right)^{(1/r)},$$

where r is a parameter that defines different types of metrics. The most commonly used distance metrics are L_1 norm for $r = 1$ (Manhattan distance), L_2 norm for $r = 2$ (Euclidian distance), and L_∞ norm for $r = \infty$ (supremum distance).

- *Cosine Similarity.* This measure is often used to characterize text document similarity (e.g., documents represented as vectors with attributes denoting the

frequency of each word in the considered document) and can be expressed as

$$\cos(x, y) = \frac{xy}{||x|| ||y||},$$

where xy is a scalar product of vectors x and y .

- *Correlation.* The standard correlation measure is commonly used to characterize the similarity between different types of data, for instance, the time series data, where the attributes represent the values of a certain parameter for different time moments. A well-known example where the correlation measure can be effectively used is the analysis of stock market data, where high correlation would mean high degree of similarity between a given pair of stocks.

Other definitions of similarity (proximity) measures are also used in practice [3]. For instance, simple matching coefficient, Jaccard coefficient, and extended Jaccard coefficient can be efficiently used to measure the similarity between binary data objects. A generalization of Euclidian distance referred to as *Mahalanobis distance* can be applied to measure similarity when data attributes are correlated. Moreover, besides defining the similarity between data objects, in some cases, it is also needed to quantify the *dissimilarity*. The aforementioned proximity measures can be also used to define the pairwise dissimilarity; therefore, all further discussion is applicable to clustering applications based on either similarity or dissimilarity. Without loss of generality, we will mostly use the term “similarity” throughout the article.

Determining an appropriate similarity measure is often a nontrivial task; however, if a suitable similarity measure is determined for a given data set, this gives one the information about pairwise proximities for all pairs of data objects. On the basis of this information, one can easily construct the $N \times N$ proximity matrix and then use the proximity matrix to create a graph with N vertices and $N(N - 1)/2$ weighted edges,

where the weights $w_{ij} = d(x^i, x^j)$ are equal to the corresponding proximity measures between data objects x^i and x^j . Note that this simple procedure would produce a complete weighted graph (with all possible edges), which can be challenging to analyze from both theoretical and computational perspectives. To reduce the edge density of the obtained graph, one can use an appropriate *sparsification* procedure that can substantially reduce the number of edges in the graph while still preserving valuable information about the data set. To achieve this, the following simple principles can be used:

- *k-Nearest Neighbor Approach.* For every vertex i , keep only the edges that connect it to its k nearest neighbors, that is, preserve k edges (i, j) with the smallest values of w_{ij} (as determined by an appropriate proximity measure) and delete the remaining edges.
- *Threshold Approach.* For every edge (i, j) , delete it if the corresponding similarity measure w_{ij} is below (or above) a specified threshold.

Applying one or both of these approaches can, in many cases, eliminate most of the edges in the constructed graph and make sure that the remaining edges preserve the most meaningful similarity relationships between the data objects in the considered data set. It should be noted that the similarity measures between each pair of vertices can be further updated to incorporate the idea of *shared nearest neighbors (SNN)*. That is, if two vertices i and j are both connected to certain number of other vertices, the weight of the edge (i, j) is increased by the number of these shared neighbors. This idea can be used for constructing the *SNN similarity graph*. In particular the concept of SNN graph has been used in the Jarvis–Patrick clustering algorithm, which essentially performs clustering on the considered data set by identifying connected components in the corresponding SNN graph [14].

In general, after the graph representing a data set has been constructed and sparsified, one can use a variety of graph-theoretic concepts and techniques to extract useful

information about the considered data set and divide the data set into a number of meaningful clusters according to the specified similarity criterion. In the next section, we concentrate on relevant concepts, definitions, and optimization problems arising in this analysis.

BASIC CONCEPTS FROM GRAPH THEORY AND THEIR DATA MINING INTERPRETATION

To facilitate further discussion, we present several formal basic definitions and notations from graph theory and discuss the interpretation of the introduced concepts from the perspective of data mining and information retrieval.

Let $G = (V, E)$ be an undirected graph with the set of N vertices V and the set of edges $E = \{(i, j) : i, j \in V\}$. Directed graphs, where the head and tail of each edge are specified, are considered in some applications. The concept of a *multigraph* is also sometimes used. A multigraph is a graph where multiple edges connecting a given pair of vertices may exist. One of the important characteristics of a graph is its *edge density*: the ratio of the number of edges in the graph to the maximum possible number of edges. As indicated in the previous section, one often needs to eliminate a substantial number of edges from a graph representing a real-life data set, so that the edge density is reduced and only the most meaningful connections are preserved.

Connected Components and Degree Distributions

The graph $G = (V, E)$ is *connected* if there is a path from any vertex to any vertex in the set V . If the graph is disconnected, it can be decomposed into several connected subgraphs, which are referred to as the *connected components* of G . In many clustering techniques, distinct connected components are interpreted as distinct *clusters* in the corresponding data set. It should be noted that although using connected components for clustering is widely used in a variety of applications, there are alternative graph-theoretic

concepts that can be utilized in clustering problems. These concepts are discussed in further sections.

The *degree* of a vertex is the number of edges emanating from it. For every integer k , one can calculate the number of vertices $n(k)$ with a degree equal to k , and then get the estimate of the probability that a vertex has the degree k as $P(k) = n(k)/n$, where n is the total number of vertices. The function $P(k)$ is referred to as the *degree distribution* of the graph. In the case of a directed graph, the concept of degree distribution is generalized: one can distinguish the distribution of *in-degrees* and *out-degrees*, which deal with the number of edges ending at and starting from a vertex, respectively.

Degree distribution is an important characteristic of a data set represented by a graph. It reflects the overall pattern of connections in the graph, which in many cases reflects the global properties of the data set that this graph represents. As mentioned above, many real-world graphs representing the data sets coming from diverse areas (Internet, telecommunications, finance, biology, and sociology) have degree distributions that follow the *power-law* model, which states that $P(k) \propto k^{-\gamma}$. Equivalently, one can represent it as $\log P \propto -\gamma \log k$, which demonstrates that this distribution forms a straight line in the logarithmic scale, and the slope of this line equals the value of the parameter γ .

An important characteristic of the power-law model is its *scale-free* property. This property implies that the power-law structure of a certain network should not depend on the size of the network. Clearly, real-world networks dynamically grow over time, therefore, the growth process of these networks should obey certain rules in order to satisfy the scale-free property. The necessary properties of the evolution of the real-world networks are *growth* and *preferential attachment* [12]. The first property implies the obvious fact that the size of these networks grows continuously (i.e., new vertices are added to a network, which means that new elements are added to the corresponding data set). The second property represents the idea that new vertices are more likely to be connected to old vertices with high degrees. It is intuitively

clear that these principles characterize the evolution of many real-world complex networks and massive data sets they represent.

From another perspective, some properties of graphs that follow the power-law model (and the corresponding data sets) can be predicted theoretically. Interesting properties of power-law graphs were studied using the theoretical *power-law random graph model* [9,13]. Among these results, one can mention the existence of a giant connected component (i.e., a giant cluster that contains $\Theta(N)$ vertices) in a power-law graph with $\gamma < \gamma_0 \approx 3.47875$, and the fact that all connected components (clusters) are small ($o(N)$ vertices) otherwise¹. The emergence of a giant connected component (or, a giant connected cluster) at the point $\gamma_0 \approx 3.47875$ is often referred to as a *phase transition*.

The size of connected components of the graph may provide useful information about the structure of the corresponding data set, since, as indicated above, the connected components would normally represent clusters of “similar” objects. In many applications, decomposing the graph into a set of connected components can provide a reasonable solution to the clustering problem. From the computational perspective, identifying all connected components in a graph is a *polynomially solvable* problem, which is especially important when the considered graphs and data sets are very large.

However, in some situations, clusters based on connected components can be extremely large (e.g., comparable with the size of the whole graph, as indicated above), and/or they may not be “tight enough,” that is, the degree of connectivity within a cluster may not be sufficient to make reliable conclusions regarding the similarity of the data objects. This motivates one to look for substantially more “robust” clusters that have specific properties of their connectivity patterns. The corresponding graph structures that address these issues are discussed in the following sections.

¹These results are valid *asymptotically almost surely* (a.a.s.), which means that the probability that a given property takes place tends to 1 as the number of vertices N goes to infinity.

Cliques and Independent Sets

Given a subset $S \subseteq V$, we denote $G(S)$ as the subgraph induced by S . A subset $C \subseteq V$ is a *clique* if $G(C)$ is a complete graph (i.e., it has all possible edges). One of the most well-known problems in combinatorial optimization, the maximum clique problem, is to find the largest clique in a graph [46].

An *independent set* is a subset $I \subseteq V$ such that the subgraph $G(I)$ has no edges. The maximum independent set problem can be easily reformulated as the maximum clique problem in the *complementary* graph $\overline{G}(V, \overline{E})$, defined as follows. If an edge $(i, j) \in E$, then $(i, j) \notin \overline{E}$; and if $(i, j) \notin E$, then $(i, j) \in \overline{E}$. A maximum clique in $\overline{G}$ is a maximum independent set in G , so the maximum clique and maximum independent set problems can be easily transformed to each other and are essentially equivalent.

Clearly, locating cliques and/or independent sets in a graph representing a data set provides important information in terms of identifying completely connected (or, on the contrary, completely disconnected) clusters. Therefore, cliques would naturally represent very *dense* clusters of similar objects. On the contrary, independent sets can be treated as groups of objects that differ from every other object in the group. This information may be important in some applications. In particular, it is often useful to find a *maximum clique or independent set* in the graph, since it would give the maximum possible size of the groups of “similar” or “different” objects.

Although finding large cliques in a graph representing a data set may be useful in terms of identifying large tightly connected clusters, an important computational disadvantage of this approach is that the maximum clique problem (as well as the maximum independent set problem) is known to be *NP-hard* [15]. Moreover, it turns out that these problems are difficult to approximate [16,17]. This makes these problems especially challenging in large graphs.

Clustering via Clique Partitioning

The problem of locating cliques and independent sets in a graph can be naturally extended to finding an optimal *partition*

of a graph into a minimum number of distinct cliques or independent sets. These problems are referred to as *minimum clique partition* and *graph coloring*, respectively. Pardalos *et al.* [18] give various mathematical programming formulations of these problems. Clearly, as in the case of maximum clique and maximum independent set problems, minimum clique partition and graph coloring are reduced to each other by considering the complimentary graph, and both of these problems are NP-hard [15]. Solving these problems for graphs representing real-life data sets is important from a data mining perspective; especially for addressing the clustering problem.

Since the data elements assigned to the same cluster should be similar to each other, the goal of clustering is achieved by finding a clique partition of the graph, and the number of clusters will equal the number of cliques in the partition.

Similar arguments hold for the case of the graph coloring problem which should be solved when a data set needs to be decomposed into the clusters of “different” objects (i.e., each object in a cluster is different from all other objects in the same cluster), that can be represented as independent sets in the corresponding graph. The number of independent sets in the optimal partition is referred to as the *chromatic number* of the graph.

Using Clique Relaxations for Graph-Based Clustering

Although cliques and independent sets address the issue of “robust” tightly connected clusters, a significant practical drawback of these structures is that they are often *too restrictive*, that is, all pairs of vertices need to be connected (disconnected). On the contrary, as mentioned above, a simple connectivity requirement may not be restrictive enough to guarantee sufficient tightness of a cluster. In an attempt to provide a trade-off between the clique-based and sparse connected component-based clusters, the concepts of *clique relaxations* have been introduced.

For instance, instead of cliques and independent sets, one can consider *quasi-cliques*

and *quasi-independent sets*, and partition the graph on this basis. Quasi-cliques are subgraphs that are *dense enough* (i.e., they have a sufficiently high edge density, but the edge density does not have to be one as in the case of cliques). Therefore, it is often reasonable to relate clusters to quasi-cliques, since they still represent sufficiently dense clusters of similar objects [19,20]. Obviously, in the case of partitioning a data set into clusters of “different” objects, one can use quasi-independent sets (i.e., subgraphs that are sparse enough) to define these clusters.

Other types of clique relaxations have also been introduced. Many of these definitions come from the studies of social networks; however, these concepts clearly have important data mining interpretations. The main idea behind these concepts is to “relax” certain properties of a clique while still maintaining sufficient connectivity and robustness characteristics of the obtained network structures. Note that in many cases the size of these clique relaxations is substantially larger than the size of cliques, which provides a significant advantage in situations when a *large tightly connected cluster* needs to be identified. In addition, clusters defined by cliques are sensitive to potential errors in data sets, since one missing edge (that may be due to a collection/measurement error) violates the whole clique structure, whereas clusters defined by clique relaxations may help avoid this drawback.

More specifically, there are three main directions for possible relaxations of the clique definition as follows:

1. *Density-Based Relaxations*: relaxing the requirement for the edge density of a clique to be 1: *quasi-cliques* (γ - dense subgraphs) [21].
2. *Degree-Based Relaxations*: relaxing the requirement that the degree of each node in a clique of size q is $q - 1$: *k-plexes* [22].
3. *Path (Diameter)-Based Relaxations*: relaxing the requirement that the length of the path between any two nodes in a clique is 1: *k-cliques* [23] and *k-clubs* [24].

A *quasi-clique* (also referred to as a γ -dense subgraph) is a subgraph that has the edge density of at least γ , where $\gamma \in (0, 1]$. Clearly, a quasi-clique becomes a clique if $\gamma = 1$. A *k-plex* is a subgraph in which the degree of each node is at least $q - k$ (assuming that q is the number of nodes in this subgraph). A *k-clique* is a subgraph where the length of the path between any two nodes is at most k (note that other nodes in this path are *not required* to belong to the *k-clique*), whereas a *k-club* is a subgraph that has a *diameter* of at most k (note that in this definition all the nodes in the paths that connect any pair of nodes within a *k-club* should also belong to this *k-club*). Obviously, for $k = 1$, a *k-plex*, a *k-clique*, or a *k-club* would also be a clique.

Although these definitions are rather straightforward and intuitively clear, mathematically rigorous studies on related optimization aspects (e.g., mathematical programming formulations for finding the largest clique relaxations in graphs) have started to appear only within the past few years. The most compact known linear 0-1 formulation for the maximum quasi-clique problem with $O(N)$ variables and constraints has been developed by Veremyev *et al.* [25]. The maximum *k-plex* problem has been addressed by Balasundaram *et al.* [26], where they provide the most compact formulation with N variables and constraints. The maximum *k-clique* and *k-club* problems and their extensions are discussed in Balasundaram *et al.* [27] and Veremyev and Boginski [28].

Utilizing clique relaxations in the context of clustering in data mining appears to be a promising approach with attractive characteristics, since it provides sufficient flexibility in terms of the tightness and size of the obtained clusters.

EXAMPLES OF REAL-WORLD APPLICATIONS

The aforementioned network-based data mining techniques have been used in a variety of real-world applications during recent years. Although the length of this article does not allow one to describe all the applications in detail, we briefly mention

several types of networks and data sets that have been addressed in the recent literature.

Biological Networks

Nowadays, representing complex biological systems as networks and studying the properties of these networks has become a very popular tool in computational biology and biomedical applications. For instance, an overview of graph-based molecular data mining approaches is presented in Fischer and Meinl [29]. A subject of particular research interest are protein-protein interaction networks that have been experimentally constructed for many known organisms. Many biological functions involve interactions between proteins at different levels, including signal transduction in cells (i.e., conversion of one kind of a signal to another inside a cell, which may play an important role in biological processes, including disease development), formation of protein complexes (i.e., stable over time structures involving multiple proteins), brief interactions between proteins involving the processes of modification of one protein by another, etc. For instance, the protein interaction network of *Saccharomyces cerevisiae*, as well as many other networks of this type, has been experimentally showed to have a *power-law structure*. Network-based clustering techniques utilizing clique relaxations (e.g., *k-clubs*) have been applied to studying these networks [27,30]. Gene expression data is also often represented in a network format, and quasi-clique-based clusters can be identified in these networks [31]. Moreover, brain dynamics data (e.g., EEG recordings from multiple electrodes located at different brain sites) can be naturally represented as a network. For instance, in Prokopyev *et al.* [32], a network-based approach of modeling brain data and identifying connected components and cliques in the considered graphs was applied to enhance the capability to identify possible epileptic seizures based on EEG time series recordings (appropriate statistical measures were used to define the similarity between EEG time series). Overall, network-based data mining approaches are receiving increased attention in biology and biomedicine.

Telecommunication/Information Exchange Networks

Large-scale information exchange networks arise in a great variety of areas, including large-scale wireless communication/sensor networks, the Internet/World Wide Web, telephone traffic networks, etc. The Internet, the World-Wide Web, and the telephone call networks (also referred to as *call graphs*) were experimentally shown to have a power-law structure. Studying the structural properties and the global organization of these networks has been addressed in recent literature. Graph theory has been applied for web search [33,34], web mining [35,36], and other problems arising in the Internet and World Wide Web. In an interesting experimental study of the world wide web, Broder *et al.* [37] used two Altavista crawls, each with about 200 million pages and 1.5 billion links and identified certain properties of the connected components of this graph. Studying the structural properties of the Internet is an exciting area of ongoing research [38]. The overall structural characteristics of the Internet are sometimes referred to as *robust yet fragile* [39], which implies the overall robustness with respect to random disruptions/errors, but potential vulnerability to targeted attacks on “hubs” (i.e., high-degree vertices).

Another well-known experimental study of a large communication network was conducted on the “call graph” representing daily telephone traffic data from AT&T telephone billing records [40]. The call graph is also very large, and the considered instance contained 53,767,087 vertices and over 170 million edges. The size of cliques and quasi-cliques in this graph were investigated, and it turned out that the size of the largest clique did not exceed 32, and the size of the largest quasi-clique with $\gamma \geq 0.5$ did not exceed 96. Since the size of the considered graphs is extremely large, the problems of identifying tight clusters, such as cliques and quasi-cliques, cannot be solved exactly due to computational challenges. Therefore, appropriate heuristic algorithms need to be applied to tackle these problems. For instance, in Abello *et al.* [40], the greedy

randomized adaptive search procedure (GRASP) [41,42] was successfully used.

Financial Networks

Although not as naturally as in the case of social and communication network data, stock market data can also be represented as a network. Let every traded stock be represented by a vertex in a network, and a given pair of vertices will be connected by an edge if the corresponding stocks exhibit a similar behavior over a certain period (this similarity can be measured in terms of correlation between the corresponding time series, and a relatively high required threshold can be set, so that an edge would be in place if this threshold is exceeded). Boginski *et al.* have previously done extensive work on studying the behavior of the entire US stock market and modeling this complex system as a large-scale network (referred to as the *market graph*) [43,44]. It was experimentally verified that these networks also have the power-law structure. Moreover, the authors rigorously studied and interpreted cliques/independent sets and clique relaxations in these networks were in terms of stock classification and choosing robust diversified portfolios. Interestingly, due to the sparse structure of this graph, the maximum clique problem could be solved exactly using an appropriate preprocessing procedure, despite the fact that the original graph contained over 6000 vertices. This study provided an innovative approach to the analysis of the structural properties of the stock market, as well as its evolution over time. In particular, it turned out that the size of the largest cluster (clique) in this graph was steadily and substantially increasing over time, which indicated that more and more stocks exhibit similar behavior in the modern financial markets.

CONCLUDING REMARKS

Network-based data mining and related OR-based techniques are promising in a variety of applications, which has been demonstrated by multiple recent studies. In this article, we briefly discussed graph-theoretic concepts and problems that are useful from both data

mining and OR perspectives; however, the research in this area is far from complete. In the coming years, we expect that this methodology will continue to be developed and utilized in new exciting applications.

Traditionally, studies of decision making have focused on situations in which people choose between outcomes that only affect themselves, such as playing a lottery where choices are described in terms of outcomes and probabilities and players have to pick the lottery that they prefer. However, many of our decisions in daily life are made in a social context in which the outcome of a decision has consequences not only for one's self but for others as well, and where we need to consider the desires and values of others before deciding.

Game theory is a collection of models for understanding such instances of interactive decision making [1]. These models make clear mathematical predictions about behavior in social situations by describing what strategies decision makers converge on as they try to maximize their payoff. To study complex social processes, such as trust, cooperation, and reputation, game theory offers a rich variety of well-designed multiplayer games. Recently, a new interdisciplinary field

has emerged, popularly known as *neuroeconomics*, which aims to better understand how people make decisions by integrating research from several different fields (for a detailed overview of the field see the handbook on neuroeconomics by Glimcher and colleagues [2]). As part of this neuroeconomic approach, researchers have begun to investigate the neural correlates of social decision making using some of these games.

In this article, we first provide a brief introduction as to how neuroeconomic studies are typically conducted. Following this, we describe the main findings of current neuroeconomic studies as they relate to game theory, and we conclude with an outline of potential future research directions in this field.

NEUROECONOMICS

Researchers in neuroeconomics have sought to investigate economic decision making in human subjects by combining a variety of methods from experimental economics, psychology, and neuroscience. These methods include (i) behavioral studies that examine how manipulation of the decision environment can affect choice, reaction time, skin conductance, or eye movements; (ii) studies with brain lesion patients that examine the consequences of abnormal brain function on decision making; (iii) experiments applying repetitive transcranial manipulation (rTMS) to temporarily disrupt activity within the brain; (iv) electroencephalography (EEG) or magnetoencephalography (MEG) studies, which measure at the scalp the electrical signals of neuronal firing; (v) pharmacological research to examine the effects of drug administration and neurotransmitters; (vi) genetic studies looking at the correlation between individual differences in the expression of certain genes and behavior; (vii) research using positron emission topography (PET) to investigate the functioning of brain structures by the use of radioactive isotopes; and (viii) functional magnetic resonance imaging (fMRI) experiments that

allow for the relatively direct measurement of real-time neural activity.

Over the last decade, the latter of these methods, fMRI, has emerged as the dominant technique in neuroeconomic studies. This method provides a noninvasive, indirect measure of the neural activity that occurs during decision making by assessing regional changes in the level of blood oxygenation. Typical fMRI experiments have a temporal resolution in the order of 1 s and a spatial resolution of 2–3 mm, which means that use of fMRI allows for the measurement of transient cognitive events, and also that relatively small structures within the brain can be imaged. A technical constraint of the method is that the blood oxygen level dependent response (BOLD) signal is rather noisy, requiring usually many trials to average the signal to a stable level. This has implications for the type of decision that can be studied, and as a consequence most game theoretic experiments undertaken with fMRI require many repetitions of the same game. This in turn means that genuine “single-shot” games (i.e., where players play only one game with only one partner) are typically not well suited to the MRI environment.

CURRENT RESEARCH

Recent research in neuroeconomics has begun to investigate the processes underlying social decision making using game theoretic paradigms. In contrast to standard behavioral studies in game theory, the neuroeconomic approach allows for the discrimination and modeling of processes that are hard to separate at the behavioral level. The combination of game theoretic models with the on-line measurement of brain activity during instances of decision making offers the promise of increasing our understanding of the processes and factors that are involved in social decision making.

An additional benefit of the neuroeconomic approach is that it has the potential to inform game theory models. This can be helpful, since actual decision behavior in game theory tasks often deviates from the models’ predictions. Game theory models assume that

players in a social context interact rationally, with full information, and that they make purely self-interested decisions. However, several decades of laboratory experiments by psychologists and economists have found that players rarely behave according to these strict game theoretic strategies [3]. Instead, players often appear to care about the welfare of others, and in addition value factors like reciprocity and fairness. Identification of the neural mechanisms underlying social interaction in game theory paradigms may result in a more precise characterization of behavior and, subsequently, game theory models may be adapted to better fit decision-making behavior.

Although neuroeconomics is still a relatively young discipline, there have already been many studies conducted that have used game theoretic approaches to gain insight into the neural basis of social decision making [4,5]). The current findings can be usefully summarized in three themes: (i) reasoning about the intentions of others, (ii) social reward, and (iii) the role of emotions in decision making, each of which is expanded upon in the remainder of this section.

Reasoning about the Intentions of Others

One focus of game theory is to model reciprocal exchange, which has been studied extensively in the laboratory with games like the trust game [6–9] and the prisoner’s dilemma game [10–12]. A trust game is played with two players. One is termed the *investor*, who is endowed with a particular monetary amount, and the other is termed the *trustee*. The investor is instructed to choose how much of her endowment she would like to pass on to the trustee and how much she will keep for herself. Once this decision is made, the experimenter multiplies the transferred amount of money by some factor (usually 3 or 4) and passes it to the trustee. At this point the trustee has the option to return the money to the investor or to keep all the money to herself. If the trustee decides to return the money, thereby honoring the trust of the investor, both players finish the game with more money than they originally had. However, if the trustee decides to keep the money and thus does not repay the trust,

the investor ends up with a loss and the trustee is the only one who benefits.

As indicated above, game theory assumes that a decision maker acts in a rational and self-interested manner, and therefore the classical economic prediction would be that a trustee in the trust game would never repay the trust of the investor. The investor, in turn, will realize this and should therefore never invest in the trustee in the first place. However, although game theory predicts no transactions to occur, behavioral experiments have consistently shown that players in the trust game do in fact engage in social interaction: the majority of investors send money to the trustees and most of the time this trust is reciprocated with payments back to the investor [3].

In a standard laboratory prisoner's dilemma game, game theoretic predictions are also usually violated. The prisoner's dilemma game is quite similar to the trust game, except that in the prisoner's dilemma game both players simultaneously choose whether to cooperate with the other or not, without knowing their partner's choice. The payoff for both players depends on the interaction of their choices, such that a player's individual earnings are highest when he or she defects and the other cooperates, with the cooperating player receiving only a small amount. Mutual cooperation, in contrast, is rewarding for both players, although individual earnings are lower than during unilateral defection. Game theory would predict that in the prisoner's dilemma game both players should decide to defect, but again, this appears to be not in accordance with the experimental data, as behavioral experiments typically find mutual cooperation occurring about half of the time. Given that standard game theoretic models are often inaccurate at describing individual decision making, how can neuroeconomic studies shed light on why human behavior appears at odds with classical economic predictions?

One potentially interesting contribution may come from how the brain perceives and computes the intentions of others, suggesting that we value not only the monetary outcome of a social interaction, but are also concerned with the message

our partner conveys by his or her behavior [13,14]. Several neuroimaging studies have shown a consistent network of areas to be involved during reciprocal exchange in both the trust game and prisoner's dilemma game [11,15,16]. For example, one of the earliest neuroeconomic studies on the trust game found that activity in the paracingulate cortex was higher when subjects played the game with another human being as opposed to a computer opponent [16] (Fig. 1a). Increased activation in this same region was also found in a following MRI study using the trust game [15]. In this study, trust building was examined by having several pairs of strangers play a nonanonymous multiround trust game, while alternating their roles as trustor and trustee. Both players were each in a separate MRI scanner, with both brains scanned simultaneously during the game. Using within- and between-brain analyses, the results showed that the paracingulate cortex was particularly active during the first phase of the multiround game for players that reciprocated their partner's decision to trust. In later stages of the game, the activity in this region decreased for this group of reciprocators. This result suggested that the paracingulate cortex is important during the early trust building phases of a relationship and that it plays less of a role during the maintenance stage of trust.

Other areas that have been consistently associated with reciprocal exchange are the posterior superior temporal sulcus and the temporal-parietal junction (Fig. 1b). Together with the paracingulate cortex, these regions have been strongly implicated in the cognitive capacity of perspective taking, an ability often termed as *theory of mind* [17,18]. The concept of theory of mind is defined as the understanding that others have of their own intentions and individual perspective of the world, and that these may differ from your own. The finding that regions related to theory of mind are involved in reciprocal exchange games suggests that players in the trust game and prisoner's dilemma game attempt to infer the strategy of their opponent and subsequently act on the belief they have about their partner's intentions. Therefore, if we perceive that a partner treats

Figure 1. Brain regions involved in decision making: (a) PCC, paracingulate cortex; VMPFC, ventromedial prefrontal cortex; $x = 46$; (b) TPJ, temporal-parietal junction; PSTS, posterior superior temporal sulcus; $x = 7$.

us badly when they have the opportunity to do otherwise, we may punish that person. However, if we believe that our partner had no choice in their behavior, we may decide to be more lenient [19]. Furthermore, these regions also seem to play a role in people's ability to determine whether the actions of others are meaningful. Many neuroimaging studies have found that game interactions with human partners produce stronger activity in theory of mind regions than identical interactions with purported computer partners [16,20,21].

Interestingly, areas important for theory of mind may also be involved in the decision to behave selfishly or altruistically. A study on altruism found that activity in the posterior superior temporal cortex correlated with individual's tendency to engage in helpful behavior [22]. Of course, in addition to the cortical network related to theory of mind, other areas may be relevant for reasoning about the intentions of others. For example, the cingulate cortex seems to represent information about which player in a trust game is responsible for a specific outcome (themselves or their partner), as its activity correlates with the agent-responsibility ("me" or "not me") of an action [23]. Future research is expected to increase our understanding on the neural mechanism of theory of mind even further by investigating what additional areas may be involved in the network as well. Furthermore, our knowledge of the specific

functions of these regions is still limited. This situation will improve as more studies in this domain will be conducted.

Social Reward

In addition to the involvement of brain structures related to theory of mind, research on the trust game and prisoner's dilemma game have indicated another area that is critical to social decision making: the striatum [7,10,11,24] (Fig. 2a). The striatum is located in the center of the brain and is a major input station of midbrain dopamine neurons that play a primary role in the processing of rewards. Single-cell recordings in nonhuman primates have demonstrated that dopamine neurons in the striatum track reward prediction errors, with unexpected rewards increasing the firing rate of dopamine cells and the omission of expected rewards leading to a decrease in the firing rate [25,26]. This reinforcement-learning mechanism is thought to be important for the learning of reward values of stimuli in the environment, thereby allowing for the improvement of choices over time.

In parallel to these primate studies, the striatum in humans is known to be involved in reward processing. Using neuroimaging and PET, researchers have discovered that this area responds not only to primary rewards such as liquids, foods, and sexual stimuli [27–30] but also to money [31,32] or more abstract rewards like reputation or

Figure 2. Brain regions involved in decision making. Locations indicated only in the right hemisphere. (a) Striatum; anterior insula; $y = 14$. (b) DLPFC, dorsolateral prefrontal cortex; $y = 45$.

status [33,34]. Importantly, reward-related activity has also been associated with social decision-making behavior. Several neuroimaging studies have demonstrated that this area responds to the decision of one's partner to either reciprocate or not reciprocate cooperation [7,10,11,24]. For example, in the prisoner's dilemma game, the striatum is activated when cooperation is reciprocated and deactivated if not reciprocated [10,11].

In addition, the striatum appears to update the trustworthiness of a partner, as activity in this area has been associated with increased cooperation or reciprocity in subsequent rounds of a prisoner's dilemma [10] or trust game [7]. A further study using the trust game paradigm showed that reward prediction errors in the striatum are significantly dependent on prior experiences, such as the moral reputation of players [24]. Providing investors with a fictional profile of the moral reputation of their partners (either morally good, bad, or neutral) before the start of a trust game resulted in reduced striatal activity when people interacted with morally good or bad partners, but not with neutral partners. Presumably this modulation of striatal activity was absent when players interacted with neutral partners because the behavior of the neutral partners was more unpredictable, as no prior information was given on their reputation. This finding

demonstrates that prior beliefs may influence the processing of social feedback information, thereby guiding future cooperation.

Reward-related activity in social decision making has been associated not only with positive, mutual cooperation. A study using PET showed that signals in the striatum were also enhanced when players punished free riders (nonreciprocators that benefit from others in a trust game), suggesting that players may derive satisfaction from punishing defectors [35]. In addition, studies have reported activity in reward networks when participants engaged in charitable donations at a personal cost to themselves [36,37]. For example, a recent study [38] provided participants with an endowed amount of money and then observed them using fMRI while they engaged in a variety of donation situations. The researchers found that reward areas were activated when participants observed a donation to a charity and, importantly, that this activation was enhanced when the donation was made voluntarily.

These neuroeconomic results are important for game theoretic approaches, as they show that regions underlying social decision making overlap with classical reward circuitry, thereby suggesting that cooperative and reciprocal behavior may be experienced directly as rewarding by players, independent of any monetary reward. This provides valuable evidence that social motivations are

indeed important when engaging in social decision making, and that we need to consider rewards other than money when constructing models of behavior in these contexts. Furthermore, the results on charitable donations are intriguing as they have relevant implications for decision making at a societal level. The fact that mandatory transfers to a charity elicit reward-related activity suggests that even taxation may produce satisfaction in certain situations.

The Role of Emotions

In addition to research on strategizing and social reward, another fruitful direction within neuroeconomics is the growing insight that emotions play a crucial role in social decision making. This idea is in contrast to classical models of economic decision making, which assume that decisions are the results of a rational and deliberate evaluation of the available choice options. However, although these models have provided a strong foundation for the development of central decision-making theories, more recent research showed that this rationality assumption is often violated [39,40].

Early work in this domain showed that patients with prefrontal brain damage and associated emotional deficits performed worse on a gambling task than healthy participants [41]. The area that was damaged in these patients was the ventromedial prefrontal cortex, a region that later was found to be essential for the activation and successful integration of emotion-related memories in the anticipation of future consequences of actions [42] (Fig. 1a). Building from this pioneering research, researchers have continued to discover that emotions play a vital role in determining decisions.

A standard game that is frequently used to illustrate that emotions have an effect on decision making is the ultimatum game. In this well-studied task, two players are required to split a sum of money that is provided by the experimenter. One of the players is deemed the proposer, and the other the responder. The proposer is instructed to specify the division of the money between the two players, and is allowed to make any split he or she wants. The responder can then accept

or reject the offer; accepting means the money is split as proposed and rejecting means that neither player receives anything. Since game theory predicts people are motivated purely by self-interest, the standard game theoretic solution for the responder is to accept any amount that is offered. The proposer should anticipate this and therefore offer the responder the smallest amount possible. However, a considerable amount of behavioral research showed that this prediction is at odds with observed behavior in the laboratory and the field: proposers generally propose an equal split and responders reject offers that are 20% of the total amount or less [43]. This very robust finding indicates that people's behavior in the ultimatum game appears not to be motivated solely by financial self-interest.

Neuroeconomic studies have attempted to specify the processes underlying the reactions of responders to unfair offers in the ultimatum game. An early study by Sanfey and colleagues [44] found that activity in the anterior insula correlated with the degree of unfairness of an offer (Fig. 2a). In addition, this region was more active for offers made by a human partner as opposed to that by a computer partner. In terms of the responder's decision, activation in this area predicted the player's decision to either accept or reject the offer, with a higher level of activity for rejections than for acceptances. The activation of the insula in the ultimatum game is particularly interesting in light of its suggested association with negative emotional states. Previous studies showed that activation in this area is consistently seen in studies to pain and disgust, and to autonomic arousal [45,46]. On the basis of these findings, anterior insula activity in the ultimatum game can be interpreted as a reflection of the responder's negative emotional state to an unfair offer.

Another brain region that was engaged during unfair offers in the ultimatum game was the right dorsolateral prefrontal cortex, a region that, in contrast to the anterior insula, usually has been associated with cognitive processes, such as the implementation of goal-directed behavior (Fig. 2b). Activation in this area was greater than activation in the insula when responders accepted unfair

offers, and less when they rejected these offers. To investigate the function of the dorsolateral prefrontal cortex in the decision to accept or reject an unfair offer, activity in this brain region has been disrupted using TMS [47,48]. After receiving TMS at the right dorsolateral prefrontal cortex, the acceptance rate of unfair offers increased, suggesting that the dorsolateral prefrontal cortex plays a causal role in the implementation of fairness-related behavior.

The finding of separable neural correlates for decisions based on emotion (rejections of an unfair offer) and deliberation (acceptance of an unfair offer) suggests that there is no unitary system at the neural level that is in control of decision making. Indeed, several neuroimaging studies showed that emotional processes seem to reliably engage a different set of brain structures than cognitive processes [49,50]. This distinction provides some support for dual-process theories, which hypothesize that decision making is the result of an interaction between an automatic, affective system and a more controlled, deliberative system. However, explaining decision making in terms of the interaction between different subsystems violates traditional economic theory, as standard economic models typically describe human behavior as being governed by a unitary process. Future economic models of decision making could usefully take into account the neuroeconomic evidence for the differential processing of emotional and deliberative information.

THE FUTURE

Many of our most important decisions are made in a social context. In the preceding sections we presented an overview of how neuroeconomics has contributed thus far to the understanding of social decision-making behavior. These findings have demonstrated that the brain has the ability to rapidly recognize and act on the intentions of others, that key regions involved in reward-based learning also underlie choices in social settings, and that emotions play a crucial role in social decision-making situations. Despite these advances, the current state of knowledge regarding the mechanisms underlying

social decision making is still rather limited. However, owing to the explosion of research in this field, and to continual refinement and advances in neuroscientific methodology, this area of research offers much promise in the years to come.

One potentially fruitful avenue of research is the investigation of how parameters of decision processes are represented in the brain using a formal modeling approach [51,52]. By connecting the parameters of formal (game theoretic) models with neural activity, a more precise characterization of the mechanisms underlying decision making can be described. In turn, by examining whether correlates of game theory parameters are present or absent in the brain, this approach may provide additional constraints on models that aim to predict social decision-making behavior.

Future studies are also likely to benefit from advancements in neuroscientific methods. For instance, fMRI measurement techniques are being improved continuously. The traditional, and still most common, approach to investigate brain function is the localization of function to specific isolated brain areas. However, a more recent way of examining neural function is to look at the structural and functional connectivity between brain areas [53]. Structural connectivity methods, such as diffusion tensor imaging, aim at inferring with the anatomical connectivity between brain regions by tracking bundles of white matter fibers linking cortical areas. Functional methods like Granger causality mapping or dynamic causal modeling investigate the effective relationship between brain areas by modeling the direct or indirect influence of one brain area over another (possibly more spatially remote) brain area. Currently, these brain connectivity methods are becoming increasingly popular and neuroeconomic data generated by this alternative approach can yield useful insights into the neural networks that are relevant for decision making.

A final interesting direction for future research is to investigate the role of hormonal and genetic factors in decision making. For instance, oxytocin, a peptide that functions both as a neurotransmitter and as a hormone,

appears to modulate a broad profile of human social behaviors. In a trust game, intranasal administration of this peptide increased the amount of money transferred by the investor [8]. A related neuroimaging study showed that this change in trusting behavior was associated with a modulation of activity in the neural systems mediating both fear and reward processing [54]. In addition, higher levels of oxytocin have been associated with more generous offers toward strangers in an ultimatum game [55,56]. Another hormone potentially of importance for social decision making is testosterone. A recent study showed that men high in testosterone were more likely to reject relatively low offers in an ultimatum game [57]. Subsequent research also examined whether testosterone levels affect the decision of the proposer. However, as is often the case in early studies contrasting findings have been reported, as one study found that artificially raised testosterone levels decreased the generosity of proposers [58], whereas another study found opposite results [59].

Researchers have also begun to examine whether genetic variation within people can explain individual differences in social decision-making behavior. Results from a twin study of the heritability of ultimatum game behavior showed that more than 40% of the variation of responder's rejection rate was explained by genetic effects. Furthermore, studies of oxytocin and vasopressin—a peptide with a structure very similar to that of oxytocin—have shown that the genetic polymorphisms for oxytocin and vasopressin receptors are associated with the allocation of funds in economic games that measure altruistic behavior [60–62].

Clearly, the future looks promising for a neuroeconomic approach of social decision making. Exploration of new research domains and the development of more advanced techniques offer fruitful opportunities for the study that combines the mathematical models of game theory with techniques of modern neuroscience. This approach will benefit the predictive accuracy of economic models by constraining their parameters based on neural substrates as

well as further our knowledge of how the brain functions.

In recent years, neuroeconomics has emerged as an exciting interdisciplinary field with the stated aim of combining knowledge from economics, psychology, and neuroscience in order to increase the understanding of decision-making behavior. The combination of these different disciplines has provided an opportunity to begin specifying the brain basis of decision-making, as well as informing theoretical models of decision-making. In addition, there is now the growing awareness that many of the findings from the field can potentially have implications for more practical decision analysis situations.

According to the classical economic perspective [1], decision makers approach choice situations by analyzing the attainable outcomes and their associated probabilities. The well-known expected utility model of decision making under risk is a good formulation of this behavior, with this model based on an axiomatic foundation that reflects a rationality assumption on the part of the decision maker [2]. Despite the model's theoretical elegance, it has been often demonstrated that it does not provide an adequate description of typical decision making, and neuroeconomic studies are beginning to demonstrate

how a better understanding of the neural processes involved can help explain these discrepancies.

In this article, we will first provide some brief details about typical methods used in neuroeconomic studies, before examining how knowledge about the valuation system in the human brain can yield insight into how decisions are made, and how this knowledge can in turn help build better models of decision and choice. We will then discuss a particularly well-known behavioral anomaly, the framing effect, and how understanding of the brain's emotional mechanisms can lead to better models of this behavior, before we conclude with some general observations about the relevance of this new discipline for decision analysis.

METHODS

One important approach to neuroeconomics has been to utilize the varied set of methods developed by neuroscientists to examine higher-level cognitive processes. These methods vary widely both in their use and in terms of what questions they can answer, but together they provide a highly flexible set of tools for examining the neural substrates of decision making. Broadly speaking, they can be divided into two types, those that observe the normal functioning brain and those that examine perturbations in these normal functions.

The most frequently used methods measure the degree of "activation" of various brain regions while people are making choices and decisions. For instance, the commonly used method of functional magnetic resonance imaging (fMRI), (see Ref. 3 for information on the method) leverages the physiological fact that changes in neural blood flow leads to corresponding changes in local magnetic properties of the brain, which in turn can be detected by an MRI machine. These blood flow changes are thought to be directly related to regional neural activity, thus providing a measure which correlates

with neural firing. The majority of the results we discuss in this article are based on fMRI studies; however, other noninvasive measuring techniques are used by neuroeconomists, such as those that measure electrical (EEG) and magnetic field (MEG) changes related to brain activity.

A different approach has been to examine the functioning of the disrupted brain to make inferences about normal behavior. Indeed, the study of decision making processes in the human brain was largely motivated by behavioral deficits that were apparent in patients with brain damage. For example, brain lesions in the frontal lobes of the brain appear to be associated with uncontrolled behavior: patients take excessive risks regardless of their intellectual capabilities or other demographic or psychological factors. The lack of an appropriate skin conductance response to emotional stimuli in this patient group set forth the idea that brain damage to the frontal lobe interfered with behavior through inappropriate integration of emotional knowledge in the decision-making process [4,5], thus providing an important initial clue as to how the brain's organization related to decision-making processes. In addition to examining the behavioral deficits of patients with lesions, there are also methods to temporarily disrupt neural processing using electrical and magnetic signals in healthy participants, such as Transcranial Magnetic Stimulation (TMS).

PREFERENCES AND VALUATION

Reward Processing in the Brain

The functioning of the human brain and the nervous system is based on millions of brain cells called neurons. In practical terms the brain is a vast network of neurons that communicate with each other. While structurally, the human brain can be divided into separate regions, some of which appear to be functionally specific, there is also much overlap between these regions.

Reward processing in the human brain is closely related to the neurotransmitter dopamine. Dopamine is produced in the brainstem and then projected to multiple

Figure 1. The striatum is located in the basal ganglia at the center of the brain. The orbitofrontal cortex (OFC) is a subsection of the frontal cortex that is specialized in valuation. The figure indicates the approximate anatomical locations of the regions of interest.

areas in the brain. Areas of the brain such as the striatum and orbitofrontal cortex (OFC) receive input from these dopaminergic neurons and are thought to process the rewarding value of stimuli (Fig. 1). Additionally, ventromedial prefrontal cortex (VMPFC) is often mentioned in this context as well. Since the anatomical definitions of medial OFC and VMPFC are somewhat overlapping, and indeed often used in parallel to refer to the same location, we adopt here for simplicity the notation of using OFC when we refer to a prefrontal region that reacts to rewards (medial OFC and VMPFC) and punishments (lateral OFC) [6].

The target regions of dopamine neurons have been shown to react to both primary and secondary rewards. Striatum activity increases with the receipt of primary rewards such as water and juice [7], and OFC activity reflects the rewarding value of stimulus in multiple different modalities like taste and olfaction [8]. In addition to primary rewards, both the striatum and OFC react to the receipt of secondary rewards such as financial incentives [9–12]. OFC is also sensitive to more subjective features of the stimuli, and is involved in the calculation of the hedonic value of rewards [6,13]. OFC even tracks modulations in the hedonic value that are driven by contextual information. In one study where participants evaluated

wine, the perceived pleasantness of the wine and the OFC activity varied as a function of retail price, though the actual wine consumed remained the same: high price increased the pleasantness estimation both in the brain and in the behavioral measures [14]. Of course, in terms of rational models, the consumption experience of identical wines should not depend on the surrounding context (price), but this research demonstrates that the brain's computations are not fully in accordance with a classical utility calculation process.

Anticipation and Evaluation of Future Rewards

In order to choose the option that provides the highest level of satisfaction, decision makers need to anticipate the rewarding value of each outcome in the relevant choice set. As this is clearly an important issue to economic decision making, anticipatory reward mechanisms were among the first topics that were widely researched in neuroeconomics. The research to date indicates that the reward circuitry in the brain demonstrates increased activation not only when rewards are obtained but also during the anticipation of rewarding outcomes [8,15,16]. Importantly, these anticipatory patterns of activation are not just correlates of the subjective value of the reward, but also have an influence on future economic choices themselves. Negative anticipatory affect during decision making is related to an increase in risk aversion, and positive anticipatory affect in contrast is associated with an increasing risk seeking attitude [17].

In addition to anticipatory reward processing, decision makers in risky choice scenarios must also take into account the probability of each outcome option in order to reach an overall estimate of the attractiveness of the prospects. In a typical experiment, participants encounter a series of uncertain prospects in turn, after which the prospects are resolved, revealing the gain or loss to the participant. As an example, in one task participants view eight cards face-down in random order, one of which is the target card. The task of the participants is to place a bet on the cards. If participants place the bet on the target card they win the bet, otherwise

they lose an equal amount of money from their total earnings. The magnitude of the outcome is manipulated by providing the participants with either 1 or 5 Euros to bet with. The probability of receiving the reward is manipulated by allowing the participants to place the bet on either just one card (low probability) or on the corners of four adjacent cards (high probability). By using this paradigm, Yacubian and colleagues showed that both the striatum and OFC encode anticipation of probabilistic rewards [18]. The findings of this experiment indicate that both the reward magnitude and also the associated probabilities are directly encoded in the valuation network itself: the striatum and OFC had higher activation levels in the high bet and high probability conditions than in the low bet and low probability conditions, respectively. Further, the results of this experiment show that the reward circuit also provides a measure for the overall desirability of a risky prospect as it encodes the expected value of a prospect, integrating the value and probability information for rewarding stimuli.

Other fMRI experiments that have studied the valuation of risky prospects have reported similar findings in reward circuitry for manipulations of outcome magnitudes and probabilities as well as for the overall expected value of the prospect [19–23]. Thus, the findings suggest that the evaluation of risky prospects is not solely performed by higher-level “rational” calculations in the brain but instead both the magnitude of the outcomes and probability of receiving them can be processed via the basic reward mechanisms of the brain.

As prior research indicates, people do not react linearly to anticipated outcomes and their probabilities. The very early work of Bernoulli showed that outcomes are processed in a subjective manner rather than relying on the objective numerical value [1]. Typically the utility associated with one additional unit decreases as the outcome level becomes higher. Intriguingly, the activation in the striatum to anticipated monetary gains appears to have the same property: the incremental additions to the strength of the striatum activity

become smaller as the magnitude of reward increases linearly [24]. This property of the striatal response is in line with the decreasing marginal utility effect which is well-characterized at the behavioral level. This finding implies that the striatum might be involved in the calculation of subjective utility of the reward rather than simply reflecting the absolute reward value. Similarly, to reward magnitude, the striatum does not react linearly to probabilities but instead it overweights small probabilities and underweights large probabilities [25]. Similar nonlinear weighting pattern of probabilities is also apparent in the behavior of decision makers [26]. These results imply that the behavioral deviations from linearity may have their roots in the properties of the reward system, both in terms of the sensitivities of the valuation and probabilistic nature of rewards and punishments.

Thus far, we have discussed the anticipatory reactions related to the expectation of financial incentives. However, it is also the case that this mechanism may underlie decisions of a nonfinancial nature, suggesting that the basic reward system may be a mechanism for most, if not all, of the typical day-to-day decisions we take. For instance, the striatum has been shown to reflect the preference for a variety of consumer products [27,28], as well as encoding the anticipatory value of hedonic outcomes [29]. The striatum activity also reflects modulations in the expected hedonic value in a similar fashion to the way the OFC encodes the influence of price on the experienced pleasantness of wines. In an fMRI study, participants evaluated the expected hedonic value of several potential vacations, after which participants were forced to make a choice between two options of similar desirability to them [29]. Behaviorally, a commitment to one of these previously equally valued options increased the estimated hedonic value of the chosen option, and decreased the valuation of the unselected one. The change in the expected pleasure of the two vacation destinations was also reflected in the striatum, with higher activity here for the chosen option than for the rejected one. Another study indicated that the subjective hedonic expectations are

indeed influenced by the basic reward processing mechanisms, with a pharmacological manipulation which increases dopamine levels, also increasing hedonic expectations for future life events [30].

Reference Dependence of Valuation

Normative decision-making models, such as the expected utility model, assume that valuation is done in respect to the total amount of wealth. One of the main insights of prospect theory [26], a descriptive theory of decision-making under risk, is that decision makers tend to value outcomes in a reference dependent manner. In accordance with this theoretical model, the brain seems to process gains and losses in a similar way. The most dramatic example of reference dependence is that the anticipated and experienced gains and losses activate different brain networks. For instance, the calculation of the expected value of a prospect has been suggested to be performed by the striatum when calculating the expectation of gains [18,22] and by more affective brain structures (amygdala) when calculating the expectation of losses [18]. In addition, the anticipation of a negative outcome has been linked to a brain structure (insula) that is often associated with processing of negative experiences such as pain [17], whereas anticipation of rewards is reflected in the striatum and OFC activity.

The reference dependence of striatum activity has been implied by multiple studies. In one early neuroeconomics study, participants played lotteries while undergoing fMRI. Two types of lotteries were used, one consisting of positive and zero outcome options, and one with negative and zero outcome options. When people received the zero outcome from the negative lottery (a relative gain), striatum activity was higher than when the zero outcome was received from the positive lottery (a relative loss) [31]. Generally, the striatum seems to process the outcomes with respect to subjective expectation [18,32], though some parts of the striatum have recently been shown to reflect reference independent calculation together with some subregions of OFC [33].

In addition to performing calculations with respect to other possible rewards, Tom

and colleagues have shown that the striatum induces nonlinear reactions to gains and losses in a task where participants made choices accepting or rejecting mixed gambles [34]. The researchers found a common network, including the striatum and OFC, that was activated for gains and deactivated for losses. These areas also showed a pattern of loss aversion, namely, that the slope of the deactivation for losses was greater than the slope of activation for gains in a majority of participants. Therefore, the striatum again demonstrates some of the properties of descriptive models of risky choice, showing loss aversion rather than the patterns predicted by classical expected utility maximization. Also of interest was that during decision making, no brain areas were found that were specifically activated by evaluation of increasing losses, in contrast to other studies that have reported increased activity in emotional regions, such as amygdala and insula, for losses [17,18]. One possible explanation for this difference is that the Tom *et al.* study restricted analysis purely to the decision-making phase (decision utility), and excluded anticipatory effects (anticipated utility) by only resolving the lotteries after the fMRI scanning.

Besides the set of possible outcomes, other contexts also influence the valuation process, such as social aspects [35] and numerical representations of financial gains [36]. Fliessbach *et al.* [35] scanned two participants simultaneously with fMRI while they performed a simple visual counting task. Participants received monetary rewards of varying magnitudes for correct performance, whereas incorrect answers had no financial consequences, and participants were informed of the performance and rewards of both players. Of interest were trials where both were correct but one of the participants received a higher reward than the other. Across reward levels, participants' striatum activity was higher when they received more than their partner relative to when they received less than the other player, demonstrating that participants evaluated their outcome relative to that of their partner, as opposed to purely evaluating the payoff.

Summary and Implications

Studies in neuroeconomics have indicated multiple properties in the valuation network of the brain that either support or contradict the assumption of rational evaluation of risky prospects. One important property of the reward circuitry is that it appears to anticipate the utility of future outcomes, providing the decision maker with necessary information for comparing the possible outcome options and selecting the most attractive course of action. Further, this circuit also informs the decision-maker of the desirability of risky prospects by integrating the subjective value and probability of expected outcomes, thus reflecting the overall attractiveness of risky alternatives. These results suggest that the valuation of risky prospects is done in the basic reward circuitry of the brain in accordance with the principles of expected utility maximization. However, when the outcome values and probabilities are manipulated, the reward circuitry does not always behave as predicted by expected utility maximization. For instance, the probabilities are represented in a nonlinear fashion in the valuation process; reward circuitry processes outcomes as gains and losses relative to a reference point; and even arbitrary contexts such as the rewards of others and the numerical presentation of the financial rewards, influence the valuation of outcomes. None of these properties meet the requirements of expected utility maximization but they are reflected in the behavior of decision makers and accounted for in descriptive models of decision making under risk [26].

In sum, the brain evidence indicates that both the evaluation of the attractiveness of risky prospects and the behavioral biases observed in these estimations, are reflected in the reward circuitry of the brain. One implication of these findings is that the evaluation of risky prospects is not controlled by higher-level deliberation, but that instead prospects are valued via more fundamental mechanisms, which also potentially explains the well-observed behavioral deviations from utility maximization.

When interpreting neuroscience findings it is important to take into account the so-called "reverse inference" fallacy, which

refers to the difficulty of inferring mental states of the decision-maker based on the activated brain regions, as one specific brain region can be involved in multiple processes. While there is a growing amount of evidence implicating striatum and OFC in the processing of rewards, it should not be concluded that these areas are reward-meters, where activity can be read off and taken as a metric of positive or negative valence. Despite this caveat, however, the investigation of how the brain computes and processes rewards and punishments offers a very useful window into basic decision making.

FRAMING EFFECT AND THE BRAIN

We have discussed above how behavioral findings such as loss aversion and reference dependent valuation can be observed at the neural level, and here we extend that by discussing another well-characterized behavioral anomaly, the framing effect [37]. The framing effect is a phenomenon where decision makers display different preferences in choice situations which are identical other than for largely irrelevant contextual effects. The effect is often described as resulting from the general tendency of decision makers to be risk averse in the gain domain and risk seeking in the loss domain. For example, imagine the following two scenarios in Fig. 2. In the first scenario you are given \$50 and then asked to make a choice between two options:

keep \$20 of the initial endowment or play a lottery where you have 40% chance of keeping the whole endowment and 60% chance of losing everything. In the second scenario, after you first received the initial endowment of \$50, you are asked to choose: either lose \$30 or participate in a lottery identical to that of the first scenario. Importantly, both of these scenarios are equivalent—they provide a choice between gaining \$20 for sure and having a 40% chance of receiving \$50. However, when people answer these questions separately, they tend to prefer the sure option in the gain domain (scenario 1: risk averse) and the lottery in the loss domain (scenario 2: risk seeking). Thus, the framing of the choice options influences the risk attitude of the decision maker and causes preference reversals. This violates the invariance principle of normative decision-making models which holds that the preference structure is independent of the phrasing of the choice options. The framing effect can be observed in multiple types of decisions and even in participant groups, such as financial planners, who are dealing with risk on a daily basis [38]. As a practical example, when people consider selling their stock investments during an economic slump, it makes a difference whether they think about the money they can save or the money they will lose in case of selling. When people think about the money they could save by selling the stocks, they often prefer the safe option of selling the

	Initial endowment	Choice	Choice in respect to total earnings
Scenario 1	\$50	Option A: keep \$20 Option B: 40% keep all 60% lose all	Option A: \$20 Option B: 40% \$50 60% \$0
Scenario 2	\$50	Option A: lose \$30 Option B: 40% keep all 60% lose all	Option A: $\\$50 - \\$30 = \\$20$ Option B: 40% \$50 60% \$0

Figure 2. Example scenarios for the framing effect. The dashed lines indicate typical choices that people make in line with the framing effect.

stocks and keeping the money (risk averse in gain domain), but when they think about the realized losses related to the sale, they prefer more risky courses of action (risk seeking in loss domain).

One possible explanation for this phenomenon is that the presence of risk in the choice situations elicits emotional reactions which intrude in the decision-making process [39]. Behavioral research suggests that, increasing the emotional salience of the choice situation strengthens nonlinearities in the valuation process [40] which leads to further deviations from risk neutrality [41], thereby strengthening the framing effects. This hypothesis of emotional involvement in framing effects was tested by De Martino *et al.* in an fMRI study, where participants made choices similar to those described above [42]. Choices where participants adhered to the standard bias (safe choice in the gain domain and lottery choice in the loss domain) were compared to those situations where participants chose in the opposite direction (lottery choice in the gain domain, and safe choice in the loss domain). This comparison showed activity in an area related to valuation and processing of emotional stimuli (amygdala; Fig. 3), supporting the hypothesis that emotional processes contribute to the framing effects. The researchers also examined which brain mechanisms were

related to resisting the framing effect, and found activity in a region that is commonly involved in conflict detection and cognitive control (anterior cingulate cortex; Fig. 3). This implies that resistance to the framing bias requires detection of conflict between the rational course of action and an emotional tendency, and regulatory control of the emotional mechanisms to override the bias.

Framing effects are not equally strong in all individuals. In a follow-up study, the researchers were interested in these differences between individuals [43]. They hypothesized that genetic variation might be able to explain these differences, and examined variation in a gene 5-HTTLPR, which has previously been shown to modulate amygdala and anterior cingulate function. The results showed that people with the short allele form of the gene demonstrated strong behavioral framing effects, which were also reflected in the activation in amygdala. In contrast, the people with the long allele variant showed a weaker behavioral effect, which was not reflected in the pattern of amygdala activity. By performing a connectivity analysis between brain regions, the researchers were able to show that the coupling between anterior cingulate and the amygdala increased when participants with long alleles were countering the framing effect. This increase in the connectivity did

Figure 3. Framing effect is related to activity in amygdala and resisting the frame involves anterior cingulate cortex (ACC) activity. The picture on the right is a slice of the brain that is cut along the midline of the head. The picture on the left is a parallel slice taken from the brain at the level of eyes. These pictures indicate the anatomical locations of the regions of interest, and do not represent data from the actual measurement.

not occur in the subjects with short alleles. On the basis of the results, the researchers claim that the participant group with the long alleles has more efficient dynamic regulatory control over the emotional amygdala reactions than the group with short alleles, which further leads to reduced behavioral framing effects. Thus, the results indicate both the role of emotional reactions and the regulation of those reactions in enhancing and controlling of behavioral framing effects, respectively, and how individual variability in the control mechanisms influences the sensitivity to the framing effects.

Summary and Implications

The fMRI experiments outlined here indicate the role of affective neural processes in driving the behavioral framing effects, and the importance of cognitive control in decreasing them. These findings imply that even when the decision situation does not have any clear emotional context, the presence of risky prospects can activate emotional brain regions. The effect of this emotional activation differs in positive and negative domains: in a positive frame involvement of emotional brain regions increases risk aversion, and in a negative frame the emotional activation leads to risk seeking attitude. Additionally, the susceptibility of individuals to framing effects differs, and these differences can at least partly be explained by genetic variation. These findings suggest that it might be possible to decrease framing effects either by decreasing the emotional reaction induced by risky prospects or by increasing the cognitive control of the decision scenario.

CONCLUSIONS

In this article, we have outlined the importance of both reward circuitry and the balance of emotional and cognitive control in the evaluation of risky prospects, and we have described how these mechanisms can be related to decision biases that have previously been observed in the behavior of decision makers. As this existing research suggests, neuroscience studies can provide insights in the decision-making processes,

and give potentially valuable information for further development of economical models. Further, a better understanding of the neural architecture underlying behavioral biases may provide opportunities to minimize the errors associated with these processes.

This work also suggests that different biases may have different fundamental causes and so might differ in how easy they are to overcome. For example, biases associated with reward mechanisms might be more persistent than the biases that arise from the imbalance of emotional and control signals. Another important role for the striatum is as part of the learning mechanism in the brain [44], which may imply that the biases that are reflected in the striatum activity are more difficult to overcome. One conception of the role of the striatum is that it is not engaged in the processing of rewards and punishments *per se*, but rather that it tracks so-called *reward prediction error*, that is, the difference between what we expect and what we receive [32], thus computing gains and losses in respect to the reference point of expected outcome. If there is a bias in the calculation of the prediction error signals, these biases are continuously reinforced in the behavior, complicating efforts to overcome the resulting behavioral biases. For example, in a loss-aversion account, if outcomes that are worse than expected are followed by an exaggerated reward prediction error signal, this will lead to the learning of loss-averse behavioral patterns for choice situations involving losses.

Despite this however, research indicates that either neural or intentional control mechanisms have the ability to reduce the behavioral biases in certain conditions [45,46]. This may be because cognitive mechanisms can overcome more affective reactions that also enhance the biases. For instance, in the case of loss aversion, there is evidence that points toward the role of emotions in enhancing the bias [28,47], and that the decision maker can reduce the influence of this emotional reaction in their decision making process by intentionally choosing to use an emotion regulation strategy [46]. As discussed earlier in this article, framing effects are also driven by emotional mechanisms. The tendency of decision makers to be

risk averse in gain domains and risk seeking in loss domains appears to be related to increased emotional brain reactions, whereas resisting the biases involves use of cognitive control mechanisms. Those individuals who have better control over their affective responses show smaller framing effects than other people. Thus, these results also indicate the importance of regulation of emotional signals in reducing biases in the decision-making process, and suggest that it is possible that the framing effects in risky decision making could also be reduced by exerting intentional control over the emotional reactions with existing emotion regulation strategies. Overall, the role of emotional reactions in inducing decision biases, and the possibilities to reduce these influences with simple instructions to the decision maker, are important aspects to take into account when designing decision support tools.

An important future step for neuroeconomics is to increase the understanding of individual variability in the sensitivity to decision biases. For developing the most efficient methods to reduce and control the decision biases on an individual level, it is important to learn more about individual differences in choice situations, which will lead to better understanding of the brain mechanisms central to decision making biases. In order to achieve a more complete picture of the neural calculations on an individual level, more attention should be paid to the functioning of larger brain networks involved in the decision making, and in particular, how the different parts of the network communicate with each other. Some initial steps toward this goal have already been taken, for instance, by categorizing people in different groups based on their genotype. Though neuroeconomics is a young field, it offers enormous potential for the better specification of decision-making behavior, and as such promises to open up interesting new avenues for decision analysis in the near future.

NEWSVENDOR MODELS

NICHOLAS C. PETRUZZI

A *newsvendor* is a firm that maximizes expected profits in the face of uncertainty. Applied in the context of inventory management, then, a newsvendor is a firm that makes available for sale a chosen quantity of its single product, given that the demand for that product is uncertain. Correspondingly, the core problem faced by the newsvendor is the question of how much quantity to supply.

Historically, the newsvendor problem (or “newsboy” problem as it originally was coined) derives its name from the metaphorical example of a street-corner newsstand stocking its inventory in preparation for the day’s random foot traffic. Because demand is uncertain at the time that the newsvendor commits to a supply for its product, the fundamental principle at the heart of this metaphor is the subtle distinction between quantity *supplied* and quantity *sold*. Indeed, a newsvendor can sell all of its supplied stock if and only if it turns out that total demand for its product meets or exceeds the total quantity supplied. If, in contrast, the quantity supplied exceeds the realized demand, then the quantity that the newsvendor sells will be constrained by the amount demanded. Thus, newsvendor models are defined in essence by the following identity:

$$\text{sales} = \min\{\text{demand}, \text{supply}\}. \quad (1)$$

MANAGING SUPPLY: THE ESSENTIAL NEWSVENDOR

Given Equation (1), let random variable D denote demand, decision variable Q denote

supply, and function $S(Q) = E[\min\{D, Q\}]$ denote expected sales. Moreover, let D be characterized by a continuous cumulative distribution function $F(\xi)$, with corresponding probability density function $f(\xi) = dF(\xi)$. Then, expected sales can be expressed as follows:

$$\begin{aligned} S(Q) &= \int_0^\infty \min\{\xi, Q\} \cdot dF(\xi) \\ &= \int_0^\infty [Q - \max\{Q - \xi, 0\}] \cdot dF(\xi) \\ &= Q - \int_0^Q (Q - \xi) \cdot dF(\xi) \\ &= \int_0^Q d\xi - \int_0^Q F(\xi) \cdot d\xi \\ &= \int_0^Q [1 - F(\xi)] \cdot d\xi, \end{aligned} \quad (2)$$

where the second from last equality in Equation (2) follows from integration by parts.

By definition, expected profit is expected revenue less expected cost. Accordingly, let c denote the newsvendor’s per unit cost of supplying its Q units, and let r denote the per unit revenue associated with selling its $S(Q)$ units. Then, the quintessential form of the newsvendor expected profit function, $\Pi(Q)$, is as follows:

$$\Pi(Q) = r \cdot S(Q) - c \cdot Q. \quad (3)$$

Given Equation (3), the newsvendor’s optimal quantity to supply, denoted Q^* , is the value of Q that maximizes $\Pi(Q)$. To that determination, note from Equation (2) that $S(Q)$ is increasing and concave in Q . As a result, $\Pi(Q)$ is concave, which implies that Q^* is the unique value of Q that satisfies the first-order optimality condition $d\Pi(Q)/dQ = 0$. That is,

$$MR(Q^*) = c, \quad (4)$$

where, from Equations (3) and (2),

$$MR(Q) \equiv d[r \cdot S(Q)]/dQ = r \cdot [1 - F(Q)]. \quad (5)$$

Note that, because $r \cdot S(Q)$ represents a newsvendor's total expected revenue function, $MR(Q)$ correspondingly represents the newsvendor's marginal expected revenue function. Likewise, because $c \cdot Q$ represents a newsvendor's total expected cost function, c correspondingly represents a newsvendor's marginal expected cost function. Therefore, Equation (4) is significant in that it extends a first-principle result of profit maximization to the analog case of uncertainty as follows: Basic microeconomic theory indicates that, in the absence of uncertainty, a firm's optimal supply of a given resource is the level at which the associated marginal revenue is equal to marginal cost. With Equation (4), newsvendor theory thus generalizes this principle by establishing that a firm should set its supply level such that marginal *expected* revenue is equal to marginal *expected* cost.

To hone this intuition, we rearrange Equations (4) and (5) to express the newsvendor's optimal supply level in its more familiar form:

$$1 - F(Q^*) = c/r. \quad (6)$$

Written this way, the ratio c/r is commonly referred to, in operations research literature, as the *critical fractile* (or, *critical ratio*). In this context, c is typically referred to as the *per unit overage cost* because it reflects the economic penalty associated with overstocking. In other words if, *ex post*, a newsvendor's chosen supply (Q) exceeds its random demand (D), then the newsvendor incurs a cost of c for each unit supplied in excess of demand ($Q > D$) that it otherwise would not have incurred. Similarly, $r - c$ typically is referred to as the *per unit underage cost*, because it reflects the net economic penalty associated with understocking. In other words, if *ex post* $Q < D$, then the newsvendor in effect forfeits a revenue of r for each unit demanded in excess of supply, which otherwise would have been sold, although that forfeiture is subsidized in the sense that the newsvendor "saves" a cost of c for each of the units not sold by not

supplying them in the first place. Given these interpretations, notice that Equation (6) can be written as $(r - c) \cdot [1 - F(Q^*)] = c \cdot F(Q^*)$. Thus, one intuitively appealing property of the newsvendor's optimal solution is that it balances the expected cost of overstocking with the expected (opportunity) cost of understocking. Correspondingly, the higher the overage cost, everything else remaining equal, the lower the optimal supply level; and the higher the underage cost, everything else remaining equal, the higher the optimal supply level.

Referring to the left-hand side of Equation (6), notice also that for any given Q , the expression $1 - F(Q)$ can be interpreted as the probability that a newsvendor will sell all of the units that it supplies. Thus Equation (6), in effect, provides an optimal stopping rule to answer the newsvendor's core question of how much quantity to supply. In particular, Equation (6) suggests thinking of a newsvendor's fundamental supply question by asking instead, at what inventory level should the newsvendor cease supplying its product? In other words, at its core, Equation (6) dictates that the question of whether or not to supply a unit boils down to the question of whether or not the unit will sell, if supplied. In a deterministic world, a firm's answer to this question is simple and obvious: If an additional unit is going to sell, then supply it; if it is not going to sell, then do not supply it. However, a newsvendor does not know *ex ante* whether or not a unit supplied will sell. Thus, to a newsvendor, the question is not will the unit sell? The question is, what is the probability that a unit will sell? Intuitively, a newsvendor should supply an additional unit if and only if the probability that the unit will sell is "high" enough. But how high is high enough to justify the supply of the unit? That is where the critical fractile comes in. Simply put, one economic interpretation of the critical fractile is that it represents a sales target, a minimum threshold to establish whether or not a marginal unit should be supplied. As long as the probability of selling a marginal unit (namely, $1 - F(Q)$) meets that threshold, the unit should be supplied. Otherwise, it should not be supplied.

Incorporating Explicit Leftovers and Shortages Effects

The quintessential form of the newsvendor's expected profit function depicted by Equation (3) provides a canonical formulation of the newsvendor problem, in that it effectively captures the fundamental *ex ante* trade-off associated with supplying a unit of its product. A general formulation, however, not only reflects the *ex ante* trade-off associated with the supply decision, but also incorporates potential economic implications of any *ex post* opportunities or repercussions associated with leftovers or shortages. Examples of such direct economic effects include salvage revenues or disposal costs associated with leftovers, and net backordering costs or loss goodwill penalties associated with shortages.

Basically, *leftovers* refers to the excess supply that results if it turns out that supply exceeds demand, and *shortages* refers to the shortfall in supply that results if it turns out that demand exceeds supply. Thus, given Equation (1),

$$\text{leftovers} = \text{supply} - \text{sales}, \quad (7)$$

$$\text{shortages} = \text{demand} - \text{sales}. \quad (8)$$

Accordingly, let $\text{LO}(Q)$ and $\text{SH}(Q)$ denote expected leftovers and expected shortages, respectively, associated with supplying Q units. Moreover, let v denote a per unit salvage value applied to $\text{LO}(Q)$ (where $v < 0$ represents a disposal cost), and let s denote a per unit penalty applied to $\text{SH}(Q)$. Incorporating these elements into Equation (3), then, expands the newsvendor expected profit function to its general form:

$$\begin{aligned} \Pi(Q) = & r \cdot S(Q) + v \cdot \text{LO}(Q) \\ & - c \cdot Q - s \cdot \text{SH}(Q). \end{aligned} \quad (9)$$

Intuitively, Equation (9) depicts the following explicit accounting of supply units and customers: Each of the Q units that a newsvendor supplies *ex ante* incurs a cost of c and then ultimately results in either a sale or a leftover. Those that result in sales ($S(Q)$), each generates a sales revenue of r ; whereas those that result in leftovers ($\text{LO}(Q)$), each

generates a salvage revenue (or disposal cost) of v . In contrast, each of the $\text{SH}(Q)$ units that the newsvendor does not supply *ex ante* effectively invokes a penalty of s as an economic proxy for customer dissatisfaction.

Although Equation (9) provides an explicit accounting of cash flows and penalties associated with a newsvendor's operations, it is convenient for analysis to rewrite Equation (9) by applying Equations (7) and (8) as follows:

$$\hat{\Pi}(Q) = [\hat{r} \cdot S(Q) - \hat{c} \cdot Q] - s \cdot E[D], \quad (10)$$

where $\hat{r} \equiv (r - v) + s$, $\hat{c} \equiv c - v$, and $E[D]$ denotes expected demand. One way to think of Equation (10) is that it provides a reinterpretation of Equation (9) based on the following metaphorical accounting of supply units and customer demands: on the supply side, the newsvendor pays an adjusted cost of $c - v$ for each of the Q units supplied. But, in turn, the newsvendor likewise receives an adjusted revenue of $r - v$ for each of the $S(Q)$ units it sells. On the demand side, the newsvendor pays a penalty s to each of the $E[D]$ customers that seeks its product. That way, if a given customer does not find a unit of the newsvendor's product in stock, that customer appropriately walks away with s as consolation. However, if that customer does find a unit of the newsvendor's product in stock, then no consolation is necessary, in which case the customer returns the s and pays the (adjusted) price $r - v$ in exchange for the unit sold. In other words, looked at from the perspective of the newsvendor's quintessential expected profit function, Equation (3), v effectively translates c into $c - v$ while correspondingly translating r into $r - v$, thus indicating that a newsvendor should define its per unit supply cost and sales revenue net of any salvage (or disposal) effects. And, s effectively translates $r - v$ into $r - v + s$ while correspondingly translating $\Pi(Q)$ into $\Pi(Q) - s \cdot E[D]$, thus indicating that a newsvendor should view the total potential cost of turning away its customer base ($s \cdot E[D]$) as its economic basis for measuring the net return on its inventory investment.

From an optimization perspective, a key implication of Equation (10) is that it is

analogous to Equation (3). In particular, because $E[D]$ is independent of Q , the Q that maximizes $\hat{\Pi}(Q)$ in Equation (10) is the same Q that maximizes $\hat{r} \cdot S(Q) - \hat{c} \cdot Q$. But, this is precisely the same function as $\Pi(Q)$ in Equation (3) except that $\hat{r}$ and $\hat{c}$ replace r and c , respectively. Correspondingly, the Q that maximizes Equation (10) is, analogous to Equation (6),

$$1 - F(Q^*) = \hat{c}/\hat{r}. \quad (11)$$

Thus, the end effect of incorporating explicit economic consequences of leftovers and shortages is a straightforward reinterpretation of the newsvendor's per unit sales revenue and supply cost. Specifically, given v and s , the newsvendor's effective revenue per unit sold is $\hat{r} \equiv (r - v) + s$ and effective cost per unit supplied is $\hat{c} \equiv c - v$. But, given $\hat{r}$ and $\hat{c}$ in place of r and c , respectively, the principle insights and interpretations following from Equation (6) apply directly.

Initial Inventory

Strictly speaking, a newsvendor problem is a single-period problem. Nonetheless, the newsvendor model is foundational to the development of periodic-review decision policies for dynamic inventory control. To help demonstrate basic principles behind this connection, suppose that a newsvendor has x usable units of its product available before establishing its total supply quantity, Q . In this context, $Q \geq x$ refers to the final supply quantity available for possible sale. Thus $S(Q)$, given by Equation (2), represents the expected sales that generate per unit revenue r , but $Q - x$ represents the incremental supply quantity that incurs per unit cost c . In other words, given an initial inventory of x usable units available to the newsvendor before its supply decision, the newsvendor's expected profit function, Equation (3), is adapted as follows:

$$\begin{aligned} \Pi(Q) &= r \cdot S(Q) - c \cdot (Q - x) \\ &= [r \cdot S(Q) - c \cdot Q] + cx. \end{aligned} \quad (12)$$

The corresponding decision problem is to maximize Equation (12) subject to the constraint $Q \geq x$.

This is a constrained optimization problem, but the unconstrained Q that maximizes $\Pi(Q)$ in Equation (12) is the same Q that maximizes $\Pi(Q)$ in Equation (3). Thus, the Q^* implicitly defined by Equation (6) can be interpreted, in this context, as the newsvendor's *desired* supply quantity. However, given the initial inventory constraint, the newsvendor's *actual* supply quantity is Q^* only if $Q^* \geq x$; otherwise, it is x . In other words, as a function of the initial inventory level, x , the newsvendor's optimal supply quantity, denoted by $Q^*(x)$, is as follows:

$$Q^*(x) = \max\{Q^*, x\}, \quad (13)$$

where Q^* is implicitly defined by Equation (6).

More important for the purpose of developing dynamic replenishment policies, however, is the newsvendor's correspondingly optimal expected profit. Accordingly, let $\pi^*(x)$ denote the newsvendor's expected profit given that the optimal supply decision, $Q^*(x)$, is implemented. Then, substituting Equation (13) into Equation (12),

$$\begin{aligned} \pi^*(x) &= \Pi(Q^*(x)) \\ &= \begin{cases} r \cdot S(Q^*) - c \cdot (Q^* - x), & \text{if } x \leq Q^*, \\ r \cdot S(x), & \text{if } x > Q^*. \end{cases} \end{aligned} \quad (14)$$

Note, $\pi^*(x)$ is continuous. Moreover, from Equation (2),

$$\frac{d\pi^*(x)}{dx} = \begin{cases} c, & \text{if } x \leq Q^*, \\ r \cdot [1 - F(x)], & \text{if } x > Q^*, \end{cases}$$

which is continuous and nonincreasing. This implies that, as a function of the initial inventory level x , the newsvendor's expected profit given that an optimal supply policy is followed, is nondecreasing and concave. This property, in particular, provides structure to the Markov Decision Processes that define periodic-review dynamic inventory models. In this respect, the newsvendor model is fundamental to the development of stochastic inventory theory.

Stochastic inventory theory is a vast and important literature linked to a pioneering

era of operations research thought. Indeed, its modern history can be traced back to seminal works and compilations from the 1950s, including, for example, Refs 1 and 2. For authoritative treatments on the current state of the theory, including its important historical developments as well as its scope and applications, we point to Refs 3 and 4. See also the sections titled “Markov Decision Processes,” “Dynamic Programming,” and “Inventory Management and Control” in this encyclopedia.

Decentralization

Strictly speaking, a newsvendor problem is a centralized-control problem. Nonetheless, the newsvendor model is foundational to the development of vertical-control models for decentralized supply chains. To help demonstrate basic principles behind this connection, suppose that the newsvendor is a firm that purchases its supply quantity, Q , from an upstream producer. In this context, Q represents the supply quantity that is first produced upstream at one firm and then transferred downstream to a different firm (i.e., the newsvendor) in exchange for consideration dictated by contractual arrangement between the two firms. Thus, r represents the per unit revenue associated with the *newsvendor's* expected sales of $S(Q)$ units, but c represents the per unit cost associated with the *producer's* production of Q units.

Given this context, first consider a *price-only* contract between the two firms [5]. A price-only contract, also referred to as a *wholesale price* contract, is defined by a single parameter; namely, a per unit wholesale price paid by the newsvendor to the producer for the exchange of the Q units. Accordingly, let w denote such a per unit wholesale price. Then, the newsvendor's expected profits and the producer's (deterministic) profits, denoted here by $\Pi_N(Q)$ and $\Pi_P(Q)$, respectively, are as follows:

$$\Pi_N(Q) = r \cdot S(Q) - w \cdot Q, \quad (15)$$

$$\Pi_P(Q) = w \cdot Q - c \cdot Q. \quad (16)$$

Note, if this were a centralized system in which the two firms were vertically

integrated, then the resulting single firm's expected profits, denoted here by $\Pi_C(Q)$, would be the combination of Equations (15) and (16). That is,

$$\Pi_C(Q) = r \cdot S(Q) - c \cdot Q, \quad (17)$$

which is precisely the expected profit function from Equation (3). Accordingly, the optimal supply quantity for the centralized system, denoted here by Q_C^* , is prescribed directly by Equation (6)

$$1 - F(Q_C^*) = c/r. \quad (18)$$

Nonetheless, in the comparable decentralized supply chain characterized by Equations (15) and (16), the newsvendor chooses its supply quantity not by maximizing Equation (17), but instead by maximizing Equation (15). Thus, the newsvendor's optimal supply quantity in the decentralized supply chain, denoted here by Q_D^* is, by analogy,

$$1 - F(Q_D^*) = w/r. \quad (19)$$

In equilibrium, $w > c$ because from Equation (16), the upstream producer otherwise would not participate in the contract due to its nonprofitability. Thus, a direct comparison of Equations (19) and (18) reveals that $Q_D^* < Q_C^*$. In other words, in the end, a decentralized supply chain in which a price-only contractual arrangement governs the exchange of units between a producer and a newsvendor undersupplies the market as compared to the corresponding centralized system. This phenomenon is called *double marginalization* [6], and its existence fuels the notion of coordination. In short, a decentralized supply chain is *coordinated*, if $Q_D^* = Q_C^*$. Correspondingly, a principle focus of supply chain coordination theory is the question of how to characterize contractual constructs that achieve or reflect coordination.

To that determination, we return to Equations (15) and (16) and replace the price-only contract ($w \cdot Q$) with an abstract contractual construct, denoted simply by $K(Q)$. Applying this abstraction, we thus adapt Equations (15) and (16) as follows:

$$\Pi_N(Q) = r \cdot S(Q) - K(Q), \quad (20)$$

$$\Pi_P(Q) = K(Q) - c \cdot Q. \quad (21)$$

With this recharacterization of the decentralized supply chain as the back-drop, note that one sufficient condition for coordination is for $K(Q)$ to be such that $\Pi_N(Q) = \alpha \cdot \Pi_C(Q) - \beta$, where α and β are constants [7]. The reason for this is as follows: If $\Pi_N(Q) = \alpha \cdot \Pi_C(Q) - \beta$, then $d\Pi_N(Q)/dQ = \alpha \cdot d\Pi_C(Q)/dQ$, which implies that $Q_D^* = Q_C^*$. Accordingly, substituting the desired outcome, $\Pi_N(Q) = \alpha \cdot \Pi_C(Q) - \beta$, into Equation (20), we thus find that $K(Q)$ is a coordinating contract if $K(Q) = r \cdot S(Q) - [\alpha \cdot \Pi_C(Q) - \beta]$. Therefore, given Equation (17), $K(Q)$ is a coordinating contract if it is of the following form:

$$K(Q) = (1 - \alpha) \cdot r \cdot S(Q) + \alpha \cdot c \cdot Q + \beta. \quad (22)$$

One way to interpret this generic form of coordinating contract $K(Q)$ is that it represents a franchise agreement. In particular, Equation (22) is reflective of an agreement in which $\alpha \cdot c \cdot Q$ denotes a transfer payment in exchange for the supply quantity provided, and $\beta + (1 - \alpha) \cdot r \cdot S(Q)$ denotes a fixed royalty payment (β) plus a variable royalty payment $((1 - \alpha) \cdot r \cdot S(Q))$ from franchisee to franchiser. However, various interpretations of Equation (22) are possible, depending on how the parameters α and β are defined. Some common variations on the theme are as follows:

- If $\alpha = 1$ and $\beta > 0$, then $K(Q) = \beta + c \cdot Q$. Specified this way, $K(Q)$ achieves coordination as a *two-part tariff* contract, and is interpreted as follows: In exchange for the transfer of Q units, the newsvendor pays its upstream producer a fixed (β) plus variable (c) price.
- If $\alpha < 1$ and $\beta = 0$, then $K(Q) = (1 - \alpha) \cdot r \cdot S(Q) + \alpha \cdot c \cdot Q$. Specified this way, $K(Q)$ achieves coordination as a *revenue-sharing* contract [7], and is interpreted as follows: In exchange for the transfer of Q units at a wholesale price that is a fraction (α) of the production cost, the newsvendor agrees

to share with the upstream producer, a complementary fraction $(1 - \alpha)$ of its sales revenue.

Alternatively, applying the identity $S(Q) = Q - \text{LO}(Q)$ from Equation (7), this variation can be expressed as $K(Q) = [c + (1 - \alpha) \cdot (r - c)] \cdot Q - (1 - \alpha) \cdot r \cdot \text{LO}(Q)$. Specified this way, $K(Q)$ achieves coordination as a *returns* contract [8]. A returns contract, also referred to as a *buyback* contract, is interpreted as follows: In exchange for the transfer of Q units at a wholesale price that includes a premium $((1 - \alpha) \cdot (r - c))$ over the per unit production cost, the upstream producer agrees to repurchase all unsold units from the newsvendor at a discounted market price $((1 - \alpha) \cdot r)$.

- If $\alpha > 1$, then $K(Q) = \alpha \cdot c \cdot Q - [(\alpha - 1) \cdot r \cdot S(Q) - \beta]$. Specified this way, $K(Q)$ achieves coordination as a *sales-rebate* contract [9,10], and is interpreted as follows: In exchange for the transfer of Q units at a wholesale price that includes a premium (α) over the per unit production cost, the upstream producer agrees to provide a rebate $((\alpha - 1) \cdot r)$ for each unit sold after a sales threshold (β) is met.

Thus, specific interpretations of Equation (22) depend not only on the specified values of α and β , but also on the specified allocation between *ex ante* transfer payments (i.e., monetary exchanges that occur when the supply quantity is transferred between firms) and *ex post* transfer payments (i.e., monetary exchanges that occur after market demand is realized). In that vein, note that, in its generic form, coordinating contract $K(Q)$ can also be interpreted as a *quantity-discount* contract in the following sense: If $\alpha < 1$ and 100% of payment transfer is *ex ante*, then the total value of that exchange, namely, $K(Q)$, increases in Q at a decreasing rate. In other words, from Equations (22) and (2), $d^2K(Q)/dQ^2 = -(1 - \alpha) \cdot r \cdot f(Q) < 0$.

The newsvendor model as a fundamental building block of the theory on supply chain contracting and coordination under uncertainty has received much attention

in operations research and management sciences literatures in recent times, particularly over the last one or two decades. For a comprehensive and insightful perspective on the current state of that theory and its practice, we point to Ref. 11. See also the section titled “Contracts in Supply Chains” in this encyclopedia.

Multiple Sourcing and Other Variants

Strictly speaking, a newsvendor problem is a single sourcing, single location, and single product problem. Nonetheless, the newsvendor model is foundational to myriad variants, extensions, and applications. Although a comprehensive taxonomy of the vast scope and applicability of newsvendor models is beyond the scope of this introductory article, we close this section on the essential newsvendor by outlining a few such variants involving multiple sourcing in particular. For further taxonomic description and analysis, we point to Ref. 12.

As one important variant, consider a network of N newsvendors, each characterized by identical economic parameters but each facing a distinct demand distribution for the same product. In this construct each newsvendor is, in effect, provided a second sourcing opportunity in the form of *ex post* transshipments drawn from leftover inventory remaining at other newsvendors in the network. However, because each newsvendor faces uncertain demand, the leftover inventory from which any given newsvendor draws its transshipments also is random. In such a case, each newsvendor’s optimal solution is dictated by the same critical fractile. Moreover, that critical fractile can be interpreted as the weighted average of the critical fractile that would be associated with a single newsvendor and a critical fractile that is representative of an aggregation of the remaining $N - 1$ newsvendors in the network. See Ref. 13 for details and Ref. 14 for a recent synthesizing analysis. See also the section titled “Warehousing and Cross-Docking” in this encyclopedia.

In a similar vein to transshipment models, the explicit incorporation of second chances to rebalance supply for a given demand population represents another prevalent

variant of the essential newsvendor model. In quick response constructs, in particular, a newsvendor is provided a second sourcing opportunity in the form of an *ex ante* adjustment to its supply quantity after a demand signal is observed but before demand is fully revealed. In such a case, the newsvendor’s optimal solution is again amenable to the critical fractile interpretation. See Refs 15 and 16 for details and Ref. 17 for a recent synthesizing analysis. See also the section titled “Supply Chain Collaboration” in this encyclopedia.

Finally, we note that another reason to incorporate multiple sourcing opportunities into the newsvendor model arises from the notion of supply-side uncertainty. In random yield and unreliable supplier models, in particular, a newsvendor’s actual supply quantity differs from its intended supply quantity. Yet, in such cases, critical fractile solutions continue to prevail to characterize the optimal solution. See Ref. 18 for an influential survey and Ref. 19 for a recent synthesizing analysis.

MANAGING DEMAND: THE PRICE-SETTING NEWSVENDOR

Although the essential newsvendor model characterizes a one-variable problem that emphasizes operational efficiency, it also is foundational to the development of joint-decision models for defining and characterizing the operations/marketing interface. To help demonstrate the basic principles behind this connection, suppose that the newsvendor not only manages its supply quantity by choosing Q , but also influences demand D by choosing its per unit selling price r . In this context, the newsvendor is a *price-setting* newsvendor. Accordingly, the newsvendor’s fundamental question of how much quantity to supply is appended to include the question of what per unit price to set.

Given this context, the newsvendor’s demand is characterized by two effects; namely, randomness (an exogenous effect) and price dependency (an endogenous effect). Therefore, we adapt the formulation of

the newsvendor's expected profit function (Eq. 3) as follows. First, let $D(r, \xi) = y(r) \cdot \xi$ denote demand, where $y(r)$ is a decreasing function defined to represent the price effect on demand, and ξ is a random variable characterized by cumulative distribution function $F(\xi)$ defined to represent the randomness effect on demand. Specified this way, $D(r, \xi)$ denotes a demand function that is multiplicatively separable in its two effects, and can be interpreted such that ξ represents the (uncertain) size of a given market and $y(r)$ represents the (deterministic) fraction of the market that is willing to pay as much as r for a unit of the newsvendor's product. (To provide a contrast, suppose that demand were specified instead, as $D(r, \xi) = y(r) + \xi$, which is a function that is additively separable in its two arguments. Then, one interpretation would be that the demand comprises two distinct markets, a price-sensitive market of (deterministic) size $y(r)$ and a price-insensitive market of (uncertain) size ξ .)

Second, let z denote a transformation of variables defined such that the newsvendor's supply quantity can be written as $Q = y(r) \cdot z$. In this transformation, z represents the newsvendor's stocking factor [20], and is introduced to replace Q as a decision variable. To give stocking factor z intuitive significance, recall from the discussion following Equation (6) that a fundamental consideration of the newsvendor is the probability that a unit, if supplied, will sell. The stocking factor, in essence, is a proxy for that probability because

$$\Pr\{D \geq Q\} = \Pr\{y(r) \cdot z \geq y(r) \cdot \xi\} = 1 - F(z).$$

Finally, let $S(Q, r) = E[\min\{D(r, \xi), Q\}] = y(r) \cdot E[\min\{\xi, z\}]$ denote expected sales, and note that analogous to Equation (2),

$$\begin{aligned} E[\min\{\xi, z\}] &= \int_0^\infty \min\{\xi, z\} dF(\xi) \\ &= \int_0^z [1 - F(\xi)] d\xi. \end{aligned} \quad (23)$$

Then, it readily follows that the price-setting newsvendor's expected profit function, denoted here as $\Pi(z, r)$, is adapted from Equation (3) as follows:

$$\Pi(z, r) = y(r) \cdot [r \cdot E[\min\{\xi, z\}] - c \cdot z]. \quad (24)$$

Given Equation (24), the price-setting newsvendor's optimal stocking factor, denoted z^* , and optimal selling price, denoted r^* , are the values of z and r , respectively, that jointly maximize $\Pi(z, r)$. Correspondingly, first-order optimality conditions require that z^* and r^* satisfy $\partial \Pi(z, r) / \partial z = 0 = \partial \Pi(z, r) / \partial r$, which from Equations (24) and (23) imply that

$$1 - F(z^*) = c/r^*, \quad (25)$$

$$\varepsilon_r(r^*) \cdot [1 - \varepsilon_z(z^*)] = 1, \quad (26)$$

where $\varepsilon_r(r)$ and $\varepsilon_z(z)$ are defined as follows:

$$\varepsilon_r(r) = \frac{-r \cdot dy(r)/dr}{y(r)}, \quad (27)$$

$$\varepsilon_z(z) = \frac{z \cdot [1 - F(z)]}{E[\min\{\xi, z\}]}. \quad (28)$$

Note that Equation (25) is analogous to Equation (6); thus it likewise can be interpreted analogously. To interpret Equation (26), note that Equations (27) and (28) represent economic elasticity measures of the price-setting newsvendor's expected sales. In particular, referring to Equation (23) and the definition of expected sales, notice that $\varepsilon_r(r)$ denotes the positive percentage change in expected sales relative to a percentage change in r , and that $\varepsilon_z(z)$ denotes the positive percentage change in expected sales relative to a percentage change in z . Thus, by definition, $\varepsilon_r(r)$ represents the price-elasticity of expected sales, and $\varepsilon_z(z)$ represents the stocking factor elasticity of expected sales. In that sense, Equation (26) prescribes an optimal balance for the price-setting newsvendor's sales elasticities.

Although Equations (25) and (26) provide necessary conditions for z^* and r^* , the sufficiency of those conditions is not necessarily guaranteed. Basically, sufficiency depends on the specifications of $y(r)$ and $F(z)$. Nonetheless, one robust test for sufficiency, which follows directly from Equations (25) and (26), is as follows [21]: If $y(r)$ is such that $\varepsilon_r(r)$ is nondecreasing in r , and $F(z)$ is such that $\varepsilon_z(z)$

is nonincreasing in z , then Equations (25) and (26) uniquely characterize z^* and r^* .

To help provide insight into this particular sufficiency test, we close by highlighting a useful parallel between the price-setting newsvendor model and a basic formulation of a monopolist's problem. In this context, we define a monopolist as a firm that, like the price-setting newsvendor, influences demand through one or more of its actions, but unlike the price-setting newsvendor, does not face uncertainty in how those actions affect demand.

Regarding the monopolist's problem, let $d(r, z)$ denote a (deterministic) demand function in which r represents selling price and z represents any other control variable that influences demand. (In economics literature, z typically is interpreted as representing "promotion" or "effort" or, simply, "services.") Moreover, let c denote the per unit cost of production, and let $k(z)$ denote the per unit cost of providing z . Then, the corresponding monopolist's problem is to maximize

$$M(r, s) = [r - c - k(z)] \cdot d(r, z). \quad (29)$$

Returning now to the price-setting newsvendor model, notice from Equation (24) that the newsvendor's problem is to maximize

$$\Pi(z, r) = [r - c - k(z)] \cdot y(r) \cdot E[\min\{\xi, z\}],$$

where

$$k(z) = c \cdot (z - E[\min\{\xi, z\}]) / E[\min\{\xi, z\}].$$

But expressed this way, the price-setting newsvendor problem is precisely the problem of the monopolist, as specified by Equation (29), except that it includes a specific functional form for $k(z)$ and it specifies the monopolist's demand function to be $y(r) \cdot E[\min\{\xi, z\}]$. This suggests, first, that the notion of stocking factor is to the newsvendor what the notion of services is to the monopolist, and, second, that the notion of expected sales is to the newsvendor what the notion of demand is to the monopolist. Thus, from an optimization perspective, what the price-setting newsvendor needs in terms of regularity conditions to assure

sufficiency, in essence, is for its expected sales function to inherit the regularity properties stipulated for the monopolist's demand function. For additional insight on this parallel, see Ref. 22. See also the section titled "Marketing/Operations Interface" in this encyclopedia.

NEWTON-TYPE METHODS

WALTER MURRAY

Stanford University,
Stanford, California

INTRODUCTION

Newton's method is famous: type it into the search in Youtube and you will get 144 videos with one having had over 30,000 hits. Despite its historic origins it would not be so well known today were it not for its widespread utility. It lies at the heart not just of methods to find roots, but also many other methods such as those for solving partial differential equations (PDEs). Even Karmakar's geometric-based algorithm [1] for linear programming that received such acclaim when it was discovered, was subsequently shown in Gill *et al.* [2] to be equivalent to Newton's method applied to a sequence of barrier functions. Newton's method also serves as a model for other algorithms. It has a theoretical purpose enabling rates of convergence to be determined easily by showing that the algorithm of interest behaves asymptotically, similarly to Newton's method. Naturally, a lot has been written about the method and a classic book well worth reading is that by Ortega and Rheinboldt [3]. Other books that cover the material here and in greater detail are Gill *et al.* [4], Bertsekas [5], and Nocedal and Wright [6].

There would not be so much to read were it not for the fact that Newton's method is only locally convergent. Moreover, as in most cases of algorithms that are only locally convergent it is usually not known *a priori* whether an initial estimate is indeed close enough. Ideally, algorithms should be globally convergent (converge from an arbitrary initial point). However, it should be remembered that proofs of global convergence do

need assumptions about the character of the problem that may not be verifiable for specific problems.

There are many approaches to incorporating Newton's method into a more complex algorithm to ensure global convergence and that is the issue we focus on here. It is somewhat more difficult to deal with the case for Newton's method to minimize a function rather than solving a system of nonlinear equations, so it is that class of problems that we give our main attention. Note that solving $f(x) = 0$ can be transformed into the minimization problem $\min_x \frac{1}{2}f(x)^T f(x)$, but minimizing a function cannot be transformed into solving a system of equations. Simply finding a stationary point by equating the gradient to zero does not do the job. Consequently, Newton's method for optimization, in addition to the deficiencies faced when solving systems of equations, needs to be augmented to enable iterates to move off saddle points. This is the key augmentation that is needed for minimization problems.

Note that there may not be a solution to $f(x) = 0$. Any algorithm will fail in some sense on such problems. It is useful to know how it fails and, should it converge, what are the properties of the point of convergence. Identifying a solution of a minimization is more problematic. We may converge to a point for which we can neither confirm the point is or is not a minimizer. That is another instance of why minimization is a more difficult problem.

Much is made, and rightly so, of Newton's method having a rapid rate of convergence. However, while little can be proved, observations show that when the Newton method converges, it usually behaves well away from the solution. It is the fact that it is a good local model of the behavior of a function that its popularity and success can be attributed. It is also the reason why alternative methods endeavor to emulate Newton's and why it is worthwhile trying to preserve the elements of Newton's method when modifying it to be robust.

We start by addressing the problem in one variable. While it does not highlight all the issues, it does illustrate the critical issue of local convergence being the best that can be achieved. In some of the text we drop the indices that denote the iteration when doing so does not cause confusion.

FUNCTIONS OF ONE VARIABLE

Newton's method for finding the root of a function of one variable is very simple to appreciate. Given some point, say, x_k , we may estimate the root of a function, say $f(x)$, by constructing the tangent to the curve of $f(x)$ at x_k and noting where that linear function is zero. Clearly, for Newton's method to be defined we need $f(x)$ to be differentiable, otherwise the tangent may not exist. Figure 1 shows a single step of Newton's method. Figure 2 illustrates that Newton's method may not give an improved estimate.

Algebraically, the method is that of approximating the nonlinear function at the current iterate by a linear one and using the location of the zero of the linear approximation as the next iterate. Consider

$$f(x) \approx ax + b,$$

where a and b are scalars. Since the two function values and their gradients are equal at x_k we have $a = f'_k \equiv f'(x_k)$ and $b = f_k - f'_k x_k$ giving

Figure 1. The tangent to $f(x)$ at x_k .

Figure 2. When f'_k is small x_{k+1} may be poor.

$$f(x) \approx f'_k x + f_k - f'_k x_k.$$

It follows that the zero of the linear function, say x_{k+1} , is given by

$$x_{k+1} = x_k - f_k / f'_k. \quad (1)$$

We can now repeat the process replacing x_k by x_{k+1} , which is Newton's method for finding the zero or root of a function of one variable. Note that the iteration given by Equation (1) is only defined if $f'_k \neq 0$ and it is this issue that is the flaw in Newton's method. It is not only when $f'_k = 0$ that is a cause of concern. If $|f'_k|$ is small compared to $|f_k|$, then the step may be so large as to make the new iterate a much worse approximation. It is not hard to construct a sequence of iterates that cycle.

Theorem 1 [Local convergence of Newton's method]. *Let $f(x)$ be a univariate continuously differentiable real-valued function on an open convex set $D \subseteq \mathbb{R}^1$. Assume that $f(x^*) = 0$ for some $x^* \in D$ and that $f'(x^*) \neq 0$. Then there exists an open interval $S \subset D$ containing x^* such that, for any x_0 in S , the Newton iterates (Eq. 1) are well defined, remain in S , and converge to x^* .*

Proof. Let α be a fixed constant in $(0, 1)$. Since f' is continuous at x^* and $f'(x^*)$ is nonzero, there is an open interval $S = (x^* - \epsilon, x^* + \epsilon)$ and a positive constant μ such that

$$\frac{1}{|f'(x)|} \leq \mu \quad \text{and} \quad |f'(y) - f'(x)| \leq \alpha/\mu, \quad (2)$$

for every x and y in S . Suppose that $x_k \in S$. Since $f(x^*) = 0$, it follows from Equation (1) that

$$x_k - x_{k+1} = (f_k - f(x^*) - f'_k(x_k - x^*)) / f'_k.$$

Hence, the first bound in Equation (2) implies

$$|x_{k+1} - x^*| \leq \mu |f_k - f(x^*) - f'_k(x_k - x^*)|.$$

From the integral mean-value theorem we have

$$\begin{aligned} f(x_k) - f(x^*) - f'_k(x_k - x^*) \\ = \int_0^1 (f'(x^* + \xi(x_k - x^*)) - f'_k(x_k - x^*)) d\xi. \end{aligned}$$

Hence,

$$\begin{aligned} |x_{k+1} - x^*| \leq \mu \\ \left\{ \max_{0 \leq \xi \leq 1} |f'(x^* + \xi(x_k - x^*)) - f'_k(x_k - x^*)| \right\} |x_k - x^*|. \quad (3) \end{aligned}$$

Thus, the second bound in Equation (2) gives

$$|x_{k+1} - x^*| \leq \alpha |x_k - x^*|$$

provided $x_k \in S$. Since $\alpha < 1$ and $x_0 \in S$, this last inequality implies that $x_k \in S$ for $k = 1, 2, \dots$, and that $\{x_k\}$ converges to x^* .

Theorem 2 [Rate of convergence of Newton's method]. *If the conditions of Theorem 1 hold, then the sequence $\{x_k\}$ generated by Newton's method converges q -superlinearly to x^* . Moreover, if $f'(x)$ is Lipschitz continuous in S , where S is defined by Theorem 1, with*

$$|f'(x) - f'(x^*)| \leq \gamma |x - x^*|, \quad x \in S, \quad (4)$$

for some constant $\gamma > 0$, then the sequence converges q -quadratically to x^* .

Proof. The linear convergence of the sequence $\{x_k\}$ to x^* is established in Theorem 1. Define

$$\beta_k = \mu \left\{ \max_{0 \leq \xi \leq 1} |f'(x^* + \xi(x_k - x^*)) - f'_k| \right\}, \quad (5)$$

and assume that $x_0 \in S$, with μ defined as in Theorem 1. The continuity of f' and the convergence of $\{x_k\}$ to x^* imply that β_k converges to zero. Since Equation (3) can be written as

$$|x_{k+1} - x^*| \leq \beta_k |x_k - x^*|,$$

the definition of q -superlinear convergence to x^* is satisfied by $\{x_k\}$. Let ξ^* denote the value of ξ for which the maximum in Equation (5) is achieved, and let y_k^* denote $x^* + \xi_k^*(x_k - x^*)$. Then

$$|f'(y_k^*) - f'_k| \leq |f'(y_k^*) - f'(x^*)| + |f'(x^*) - f'_k|. \quad (6)$$

Applying Equation (4) in Equations (6) and (5) gives

$$\beta_k \leq 2\mu\gamma |x_k - x^*|.$$

Hence, $\{x_k\}$ satisfies the definition that the rate of convergence to x^* is at least quadratic.

It should be stressed that Newton's method can converge even if $f'(x^*) = 0$. For example, suppose $f(x) = x^3$. Clearly $x^* = 0$. The Newton iteration is

$$x_{k+1} = x_k - x_k^3 / (3x_k^2) = 2x_k / 3,$$

which obviously converges to 0, but at a linear rate. We can see from Fig. 2 that simply shifting the function to be $x^3 - 1$ does not result in such a smooth set of iterates, although in that case when it converges, it does so at a quadratic rate. What this example also illustrates is that the interval of fast convergence may well be small when $f'(x^*)$ is small. In the example above, x^* is a point of inflection. It could well be that x^* is a local minimizer or a local maximizer of $f(x)$ in which case there exists a neighboring function that does not have a zero in the neighborhood of x^* . Typically, when problems are solved numerically, the best that can be achieved is to

solve exactly a neighboring problem. Even if the iterates converge numerically to a point for which $|f(x)|$ is small, there will remain some uncertainty as to whether a zero exists when $f'(x^*)$ is also very small. In the case where the function changes sign at x^* this may be checked. More importantly, knowing an interval for which the sign of the function at the end points are different provides a means of modifying Newton's method to enable it to find a zero. Specifically, when the Newton step lies outside the interval it needs to be replaced by a point in the interval. A more sophisticated approach is to replace the Newton step even when it lies in the interval. Since we are taking the Newton step from the better of the two endpoints we "expect" the next iterate to be close to that point.

A Hybrid Algorithm

If an interval is known, say $[a, b]$, at which $\text{sign}(f(a)) = -\text{sign}(f(b))$, then a zero may be found by the method of bisection. The function is evaluated at the midpoint of the interval and the end point of the same sign then discarded to give a new interval half the previous size. The bisection point is optimal in the sense it gives the best worst case performance. This approach may be combined with Newton's method by discarding the Newton iterate whenever it lies outside of the interval in which it is known a root lies. Some care needs to be exercised to ensure the algorithm converges and to ensure that the convergence is not very slow. For example, we need to reject the Newton iterate even if it lies within the interval if it is very close to an end point. When performing bisection alone, the optimal placement of the new iterate is the midpoint. When combining the method with Newton, we are assuming that eventually Newton's method will make bisection steps unnecessary. If the bisection step is such that the *best* iterate remains the same, then at the next iteration we will perform yet another bisection step. Consequently, we may wish to choose instead, a point that looks more likely to replace the best iterate by making it closer to that iterate than the bisection point.

Modifying Newton's Method to Ensure Global Convergence

For one variable, the hybrid algorithm described above is probably the best way to go. However, interval reduction does not generalize to n dimensions so it is worthwhile to discuss other means of making the method more robust. A necessary feature we need to ensure is the existence of the iterates. One way of achieving that is to replace the Newton iteration whenever $|f'_k| \leq \delta$, where $\delta > 0$. For example,

$$x_{k+1} = x_k - f_k/\beta, \quad (7)$$

where $\beta = \text{sign}(f'_k)\delta$ if $|f'_k| \leq \delta$, otherwise $\beta = f'_k$. This modification alone does not ensure convergence. What is needed is something that ensures the iterates are improving. One means of defining improvement is a reduction in $f(x)^2$. We could have chosen $|f(x)|$, but $f(x)^2$ has the advantage of being differentiable. The basic idea is to define the iterate as

$$x_{k+1} = x_k - \alpha_k f_k/\beta, \quad (8)$$

where α_k is chosen such that $f_{k+1}^2 < f_k^2$. We need something slightly stronger to prove convergence, but it is enough to choose $\alpha_k = \frac{1}{2}^j$, where j is the smallest index ≥ 1 such that $f(x_k + \frac{1}{2}^j f_k/\beta)^2 < f_k^2$. Determining α_k is a common procedure in n -dimensional problems and more elaborate and more efficient methods are known than the simple backtracking just described. However, they also require more elaborate termination conditions, which we discuss later.

Minimizing a Function of One Variable

Consider now the problem of

$$\min_x f(x).$$

As noted earlier, we could apply Newton's method to $g(x)$, where $g(x) = f'(x)$. The Newton iteration is then given by

$$x_{k+1} = x_k - g_k/g'_k. \quad (9)$$

Clearly, we can only expect this iteration to converge to x^* , where $g(x^*) = 0$. However, if

$g'(x^*) < 0$ we would know that x^* is a maximizer and not a minimizer. Another interpretation is that we are approximating $f(x)$ by a quadratic function, for example

$$f(x) \approx \frac{1}{2}ax^2 + bx + c.$$

The parameters a, b , and c may be determined by the three pieces of information f_k, g_k , and g'_k . The next iterate is defined to be the minimizer of this quadratic function. However, when $a = g'_k < 0$, the quadratic function does not have a minimizer. Even when $a = 0$, unless $b = 0$, this function does not have a minimizer. An essential first step then is to define the Newton iteration for minimizing a function as a modification to Equation (9), namely

$$x_{k+1} = x_k - g_k / |g'_k|. \quad (10)$$

In essence, we reverse the step when g'_k is negative and go in the direction away from the maximizer. To amend the algorithm when $|g'_k| = 0$ or is very small, we can make the same changes as in Equation (7) except $\beta = \delta$ if $|g'_k| \leq \delta$, otherwise $\beta = |g'_k|$. Also α_k is chosen to reduce $f(x)$ rather than $g(x)^T g(x)$. However, there is one more case to consider and that is if $g_k = 0$. In this case, if $g'_k = 0$, we may not be able to make progress. If $g'_k < 0$ then we are at a maximum and a tiny step in either direction from x_k will produce a new iterate x_{k+1} such that $f_{k+1} < f_k$.

As in the case of finding a zero, we could also combine Newton with an interval reduction algorithm such as bisection. We know a minimizer exists in an interval $[a, b]$ if $g(a) > 0$ and $g(b) < 0$. Consequently, we can always maintain an interval containing a minimizer by discarding the appropriate end point. There is a minor complication if $g(x) = 0$ at the new point. Also, if there is more than one minimizer in the interval there may be a choice.

FUNCTIONS WITH N VARIABLES

The extension to n variables is straightforward. The Newton iteration for $f(x) = 0$ becomes

$$x_{k+1} = x_k - J_k^{-1} f_k, \quad (11)$$

where $J_k \equiv J(x_k)$, and $J(x)$ is the Jacobian matrix of $f(x)$. Likewise, the iteration for $\min_x f(x)$ is

$$x_{k+1} = x_k - H_k^{-1} g_k, \quad (12)$$

where $H_k \equiv H(x_k)$, and $H(x)$ is the Hessian matrix of $f(x)$. Obviously, the iterations are only defined if the relevant inverses exist. The conditions for convergence and for the rate of convergence to be at least quadratic in the n -dimensional case is similar to that for the one-dimensional case. Rather than an interval we now require $J(x)$ (and $H(x)$) to be nonsingular in a ball about x^* . Despite being in n -dimensions, the Taylor expansions used in the proofs are still in one dimension since we are relating x_{k+1} to x_k along the vector connecting them.

Rather than define the iterations as in Equations (11) and (12), it is more typical to define them as

$$x_{k+1} = x_k + p_k,$$

where p_k is thought of as the “Newton step.” When modified as

$$x_{k+1} = x_k + \alpha_k p_k,$$

then the Newton step p_k is viewed as a search direction and the scalar $\alpha_k > 0$ is the step length. We are considering the Newton step as a trial to be rejected if it proves worse (in some sense) than the current approximation.

Rather than using inverses, we define p_k as the solution of a system of linear equations, which for solving $f(x) = 0$ becomes

$$J_k p_k = -f_k,$$

and for minimizing a function

$$H_k p_k = -g_k.$$

In the case of minimizing, the iteration only makes sense when H_k is positive definite. Unlike spotting whether g'_k is positive, determining whether a matrix is positive definite is nontrivial. Since H_k is symmetric, if it

was known to be positive definite we would usually determine p_k using Cholesky's algorithm. The algorithm can fail when H_k is indefinite and it is that failure that is the simplest way of determining whether or not H_k is positive definite.

LINESEARCH METHODS

Cast in the manner above, Newton's method may be viewed to be in the class of linesearch methods for minimizing a function [4]. From now on, we shall treat the problem of $f(x) = 0$ as $\min_x \frac{1}{2}f(x)^T f(x)$. A key requirement for linesearch methods is that p_k is a direction of *sufficient descent*, which is defined as

$$\frac{g_k^T p_k}{\|g_k\| \|p_k\|} \leq -\epsilon, \quad (13)$$

where $\epsilon > 0$, and $\|a^2\| \equiv a^T a$. This condition bounds the elements of the sequence $\{p_k\}$ from being arbitrarily close to orthogonality to the gradient. Typically methods are such that p_k is defined in a manner that satisfies Equation (13) even though an explicit value of ϵ is not known.

The other key requirement is that the step length α_k is chosen so as to not be too large or too small. This may be achieved by a suitable termination condition in the search for α_k . The termination criteria used in the optimization routine SNOPT [7] is

$$|g(x_k + \alpha p_k)^T p_k| \leq -\eta g_k^T p_k, \quad (14)$$

where $0 < \eta \leq 1$. Typically, η is chosen in the range $[.1, .9]$. This termination criterion ensures the step α_k is not too small. Usually, it will also ensure it is not too large. However, to be absolutely sure, we need an additional condition and

$$f(x_k + \alpha p_k) \leq f_k + \mu \alpha g(x_k + \alpha p_k)^T p_k, \quad (15)$$

where $0 < \mu < \frac{1}{2}$ will suffice. Typically, μ is chosen quite small and as a consequence, this condition is almost always satisfied once Equation (14) is satisfied. To find a step that satisfies Equation (14), one can search for a minimizer along p_k and terminate at the first

point that Equation (14) is satisfied. Since we are generating iterates that decrease $f(x)$, it follows that Equation (15) is satisfied with μ replaced by $\epsilon_k > 0$.

It can be shown that under modest assumptions, linesearch methods generate a sequence such that $\lim_{k \rightarrow \infty} g_k = 0$. For nonlinear equations, since $g_k = J_k^T f_k$, it implies $f_k \rightarrow 0$ provided J^* is nonsingular. In the minimization case we are only sure we are at a minimizer only if $\lim H_k = H^*$ and H^* is positive definite. When H^* is positive semidefinite with at least one zero eigenvalue and when higher derivatives of $f(x)$ are unknown, there is usually nothing further that can be done to confirm the iterates have converged to a minimizer. Indeed, it is not known just how many orders of higher derivatives will be needed to resolve the issue.

A more general issue is what do in any iteration when either J_k is singular or H_k is indefinite since under such circumstances, the Newton step is not necessarily a sufficient descent direction. If p_k is defined to be the solution of a system

$$B_k p_k = -g_k,$$

where $\{B_k\}$ is a sequence of bounded positive definite symmetric matrices whose condition number is also bounded (smallest eigenvalue bounded away from 0), then $\{p_k\}$ is a sequence of sufficient descent directions. It is easy to see why. Let A be a symmetric matrix with eigenvalues

$$0 < \lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_n.$$

Let p and g denote vectors in $\Re^n$ such that $Ap = -g$. From the definition of the smallest eigenvalue λ_1 , we have

$$u^T A u \geq \lambda_1 \|u\|^2.$$

From and the relationship $Ap = -g$ and the above inequality we have

$$\begin{aligned} -g^T p / (\|p\| \|g\|) &= p^T A p / (\|p\| \|g\|) \\ &\geq \lambda_1 \|p\| / \|g\|. \end{aligned}$$

Moreover, from norm inequalities we may assert that

$$\|g\| = \|Ap\| \leq \|A\| \|p\| = \lambda_n \|p\|.$$

Using the bound gives

$$-g^T p / (\|p\| \|g\|) \geq \lambda_1 / \lambda_n.$$

Applying this result to each matrix in the sequence $\{B_k\}$ gives

$$\cos \theta_k = -g_k^T p_k / (\|g_k\| \|p_k\|) \geq \lambda_1^{(k)} / \lambda_n^{(k)} \geq 1/M.$$

Consequently, $\{p_k\}$ is a sequence of sufficient descent directions as required. The main idea on how to modify the Newton system defining p_k is to ensure that it is the solution of a system that has the same properties as a B_k .

Consider first the nonlinear eqnarray case. When J_k is nonsingular, the search direction p_k is the solution of

$$J_k^T J_k p_k = -J_k^T f_k.$$

Obviously, if J_k is singular then so is $J_k^T J_k$. However, we may modify the symmetric system above by adding a multiple of the identity giving

$$(J_k^T J_k + \lambda_k I) p_k = -J_k^T f_k.$$

The above system will be nonsingular provided $\lambda_k > 0$. Hence, p_k is always well defined and, provided λ_k is chosen appropriately, is a sufficient descent direction for $\frac{1}{2}f(x)^T f(x)$. There are details that need explaining such as how best to solve this system and how to determine a good value for λ_k , but the issue of convergence is resolved. When $J(x^*)$ is nonsingular then there exists an index, say K , such that for $k \geq K$ we may set $\lambda_k = 0$. By doing so, the terminal search directions are pure Newton's steps.

We have left one detail out and that is the assumption that $\alpha_k = 1$ for $k \geq K$. Since we do not in general know K , when we compute the pure Newton direction in the neighborhood of the solution, we need the linesearch procedure to automatically take the unit step. It is easy to show this will happen provided the initial step taken is 1.

Setting $\alpha = 1$ in the LHS of Equation (14) and noting there exists a constant $M < \infty$ such that $\|g(x_k + p_k)\| \leq M \|g_k\|^2$ when $J(x^*)$ is nonsingular, we get

$$\begin{aligned} |g(x_k + p_k)^T p_k| &\leq \|g(x_k + p_k)\| \|p_k\| \\ &\leq M \|g_k\|^2 \|p_k\|. \end{aligned} \quad (16)$$

Since p_k is a sufficient descent direction, then the RHS of Equation (14) satisfies

$$-\eta g_k^T p_k \geq \eta \epsilon \|g_k\| \|p_k\|. \quad (17)$$

Since $\lim \|g_k\| \rightarrow 0$ it follows there exists K for which the unit step satisfies Equation (14) for $k \geq K$. Note that for the problem $f(x) = 0$ we have $g_k = J_k^T f_k$.

By a similar argument we can show that Equation (15) is also satisfied, which gives us the desired result.

Obtaining a Direction of Sufficient Descent from the Newton Equation

It may be thought that a simple way would be to solve the Newton equations and then reverse the direction if $g^T p > 0$. While this works in the one-variable case, it is flawed in the n -dimensional case. It is not hard to see why although doubtless this approach is still used. Suppose we have two variables and $f(x_1, x_2)$ is a separable function, that is $f(x) = f_1(x_1) + f_2(x_2)$. It follows that the Hessian is a diagonal matrix. Suppose $H_{1,1} > 0$ and $H_{2,2} < 0$ and the Newton step is p . In the x_1 variable, the step p_1 is correctly stepping toward the minimizer, while the step p_2 is stepping away from a minimizer. It could happen that $-p_1 g_1 < p_2 g_2$ in which case p is not a descent direction. What we would do if we knew this was a separable function is reverse the sign of p_2 only. More generally, what we wish to do is to preserve the Newton step in the subspace for which the H is positive definite and reverse it in the subspace it is not. We now explain how to do that. Note that reversing the sign of p does not give an assured descent direction since $p^T g$ could be zero even when g is not zero.

Consider the spectral decomposition: $H = V \Lambda V^T$, where V is the matrix of eigenvectors, $\Lambda = \text{Diag}(\lambda)$, and λ is the vector of

eigenvalues. Define

$$\bar{H} \equiv V\bar{\Lambda}V^T,$$

where $\bar{\lambda}_i = |\lambda_i|$, if $|\lambda_i| \geq \delta$, otherwise $\bar{\lambda}_i = \delta \geq 0$, and $\bar{\Lambda} = \text{Diag}(\bar{\lambda})$. A means of achieving our objective is to define p as

$$p \equiv -\bar{H}^{-1}g.$$

Provided the minimum eigenvalue of H^* is bigger than δ then Newton steps will be taken in the neighborhood of the solution. It may be thought that δ could be allowed to converge to zero as $g_k \rightarrow 0$, which would assure Newton's steps will always be taken in the neighborhood of the solution, provided H^* is positive definite. For example, we could define $\delta \equiv \min\{|g_k|, \epsilon\}$, where $\epsilon \geq 0$. However, in practice p is computed numerically and the error in the computed solution will overwhelm the Newton step when H^* is ill-conditioned. Indeed, the error analysis establishing that Cholesky is a stable algorithm assumes the matrix is sufficiently positive definite.

The drawback of the scheme above is that when n is large it is expensive both in computational effort and memory to compute the spectral decomposition. When H is sufficiently positive definite, it is also unnecessary. Since Cholesky is so cheap it is always worth trying first. An alternative is to compute a direction based on modifying the Cholesky factorization. Cholesky fails on indefinite matrices due to the need to compute a square root of a negative number when computing the diagonal elements of the factor. An obvious change is to define the diagonal elements in the same vein as the modification made to the eigenvalues. If no zero pivots occur, the factorization LDL^T exists, where L is a unit lower triangular matrix and D is diagonal. We can now define $\bar{D}$ in relationship to D in the identical manner to the relationship of $\bar{\Lambda}$ to Λ . It can be shown that $\bar{H} \equiv L\bar{D}L^T = H + E$, where E is also diagonal. In practice, the occurrence of a zero diagonal is of no consequence since should one arise, it is replaced by δ . Unfortunately, it can be shown that the bound on $\|E\|$ is $O(1/\delta)$ [4].

In order to obtain a Cholesky factor that is not close to being unbounded, it is necessary to perform the column form of the algorithm. The basic idea is not simply to alter pivots that are tiny or negative but to alter any pivot for which it is necessary to ensure that the magnitude of the elements of the Cholesky factor are *suitably* bounded. If on first computing an element it exceeds a prespecified bound, say β , then it is recomputed using an increase to the pivot that makes it match the bound. Care needs to be exercised in defining β to ensure that matrices that are sufficiently positive definite are not modified. Let $\bar{R}$ denote the Cholesky factor generated by this algorithm, then β is chosen such that $|\bar{R}_{i,j}| \leq \beta$, where

$$\beta^2 = \max\{\gamma, \xi/n, \delta\},$$

γ and ξ are the largest in modulus of the diagonal and off-diagonal elements of H respectively, and as before δ is some small positive scalar. It can be shown [4] that $\bar{H} \equiv H + E$, E is a diagonal matrix, $\|E\|$ is bounded and $\bar{H}$ has a bounded condition number. The algorithm requires almost the same computational effort as the regular Cholesky algorithm. Let $\bar{R}_k$ denote the Cholesky factor of $\bar{H}_k$. It follows a suitable sequence of sufficient descent directions, $\{p_k\}$, which are obtained by solving

$$\bar{R}_k^T \bar{R}_k p_k = -g_k.$$

When H^* is sufficiently positive definite, then in the neighborhood of the solution $H_k = \bar{H}_k$ and Newton steps are taken.

Generally using a modified direction as defined avoids saddle points. We are deliberately defining the direction not to be a step to such points. However, we could start at one or end up at one by chance. There are also problems [8] that have a form of symmetry that results in the gradient being in the space of the eigenvectors corresponding to the positive eigenvalues of H . It is a consequence of variables whose values, when they are switched, give the same objective. For such problems, the only way of breaking the tie is to use a direction of negative curvature (DNC).

Directions of Negative Curvature

If $g = 0$, then there is no direction of descent and if H is indefinite then x is a saddle point. The key to moving off a saddle point (or avoiding converging to one) is to use directions of negative curvature. A vector d is termed a DNC if $d^T H d < 0$. Obviously, the Hessian needs to be indefinite for such a direction to exist. It may be thought that it is relatively easy to find such a direction and in some cases it is. If H has half its eigenvalues that are negative and equal in value to the positive set then a random direction has a 50% chance of being a DNC. However, it can be shown [9] that the probability is extremely small when the number of positive eigenvalues dominate (approximately 10^{-14} when there are 99 eigenvalues of 1 and one of -1). Typically, in optimization problems there are only a few negative eigenvalues (the iterates are converging to a point the Hessian is positive semidefinite) and even these are small. A single large negative eigenvalue would signify that there is a DNC along which the objective will decrease rapidly and we are rarely that lucky.

Unlike directions of descent, there is a "best" DNC; namely, the eigenvector corresponding to the smallest eigenvalue. If the smallest eigenvalue is not unique, then any vector spanned by the set of corresponding eigenvalues is equally good. It is best in the sense that this direction has the smallest value of $d^T H d / d^T d$ and it is independent of a linear transformation of variables. A DNC predicts a potentially infinite reduction in the objective. Of course, in practice the step will be finite but there is no good initial estimate of what the finite step should be. This contrasts with a direction of descent which is typically derived from a positive definite quadratic model for which the unit step is the predicted to be optimal.

In order to show the iterates will converge to a point for which the Hessian is at least positive semidefinite, it is necessary for the DNC to be a direction of sufficient negative curvature. A sufficient condition for $\{d_k\}$ to be a sequence of directions of sufficient negative curvature is that

$$d_k^T H_k d_k \leq \theta \lambda_{\min_k} d_k^T d_k,$$

where $\lambda_{\min_k}$ is the smallest eigenvalue of H_k , and $\theta > 0$. Obviously $\theta \leq 1$. What the requirement does is to prevent d_k from becoming arbitrarily close to being a direction of zero curvature.

If d_k is a DNC then so is $-d_k$. The sign is chosen so that $d_k^T g_k \leq 0$. If $H(x^*)$ is positive definite, then there exists a index K such that for $k \geq K$ then $d_k = 0$.

A DNC may be computed from the modified Cholesky factorization. It can be shown an index, j , exists (it can be identified during the factorization) such that d , where

$$\bar{R}d = e_j, \quad (18)$$

is a DNC. However, it is not a direction of sufficiently negative curvature. Fortunately, this is of little consequence. Rather than applying the modified Cholesky algorithm to H it is better to apply it to $H + \delta I$, where $\delta > 0$ is suitably small. This modification serves a number of purposes. If this matrix is indefinite, then Equation (18) does give a sufficient DNC. When H^* is singular and positive semidefinite, it avoids tripping the modifications and from a getting a DNC that is not needed in the neighborhood of x^* . Given a DNC, it can be improved by using it as a starting point to minimize $d^T H d / d^T d$; for example, by just using a single pass through all the variables of a univariate search [9].

An issue is how best to use a DNC. An obvious choice is to define the search direction as

$$\bar{p} = p + d,$$

where p is a direction of sufficient descent. It is prudent to have scaled d . There are various schemes that can be used but the general principle is that if $d^T H d / d^T d$ is small then $\|d\|$ should be small.

It can be shown under suitable assumptions that this algorithm converges to a point satisfying the second-order conditions necessary for optimality.

TRUST-REGION METHODS

An alternative to modifying the Hessian is to minimize the quadratic approximation subject to a limit on the size of the step. This

is similar to using the interval to limit the step in problems with one variable. However, unlike the one-variable case, the solution does not usually lie within the limit. If at this new point the objective is not an improvement, then the limit is reduced. We wish to solve

$$\min_s \{\psi(s) \equiv \frac{1}{2}s^T H s + g^T s \mid s^T s \leq \Delta\}, \quad (19)$$

where $\Delta > 0$. Clearly a minimizer exists. It can be shown [6] that there exists a scalar $\lambda \geq 0$ such that the global minimizer, s^* , satisfies

$$(H + \lambda I)s^* = -g, \quad (20)$$

where $H + \lambda I$ is positive semidefinite and $\lambda(s^{*T}s - \Delta) = 0$. It is rare for $H + \lambda I$ to be singular. It is immediately apparent that the definition of s^* is similar to that of p , since the matrix is symmetric, at least positive semidefinite and is a diagonal modification of H . If H is positive definite and the solution of $Hs = -g$ is such that $s^T s \leq \Delta$ then s^* is the Newton step. When $f(x + s^*) \geq f(x)$ the step is rejected and the system (Eq. 20) is resolved with a smaller value of Δ , typically $\Delta \rightarrow \Delta/2$. It can be shown only a finite number of reductions need be taken. If a satisfactory step is obtained without the need to reduce Δ and $\psi(s^*)$ is a reasonable prediction of $f(x) - f(x + s^*)$ then Δ at the next iteration is increased, typically $\Delta \rightarrow 2\Delta$. It can be shown under typical assumptions that the sequence generated by the trust-region algorithm converges to a point satisfying second-order necessary conditions for optimality. It can also be shown that when H^* is positive definite that Δ does not converge to zero. Consequently, in the neighborhood of the solution Newton steps are taken.

In order to solve Equation (20), it is necessary to determine λ . To do so requires solving Equation (20) with estimates of λ . Also if Δ is unsatisfactory, the process has to be repeated, which requires more solutions of Equation (20). It is not necessary to determine λ accurately and often Δ is satisfactory. Nonetheless it is clear a trust-region algorithm which requires more solutions of similar linear systems than a linesearch method.

Note that when $g = 0$ and H is indefinite, then the solution of Equation (20) is the eigenvector corresponding to the minimum eigenvalue (assuming it is unique).

GRADIENT-FLOW METHODS

Unlike the other two classes of methods, these are not in widespread use. The methods were originally proposed by Courant to solve PDEs. Their simplest form is to compute the arc $x(t)$, where $x(t)$ satisfies

$$x'(t) = -g(x(t)) \text{ and } x(0) = x_0. \quad (21)$$

The minimization problem has been replaced by the problem of solving a system of nonlinear differential equations. This approach is grossly inefficient. The method is made reasonable when $g(x(t))$ is approximated at x_k by $g_k + H_k(x(t) - x_k)$. The idea now is compute x_{k+1} by searching along the arc $p(t)$, where $p(t)$ is the solution of a linear system of differential equations:

$$p'(t) = -g_k - H_k p(t) \text{ and } p(0) = 0. \quad (22)$$

The connection to Newton's method is now apparent. When H_k is positive definite, the arc is finite and the end point is the Newton step from x_k . If $H(x^*)$ is positive definite, then when the iterates are in a small neighborhood of the solution, the Newton step is taken. An interesting property of this approach is that the arcs and iterates generated are invariant under an affine transformation, a property that is typically not true for either linesearch or trust-region methods when H_k is not positive definite for all k .

ESTIMATING DERIVATIVES

For minimization problems, Newton-type methods assume the availability of second derivatives. When these derivatives are not available there are alternatives such as quasi-Newton methods. Usually these alternatives are to be preferred although there are problems where using the Newton-type methods described, except with the Hessian approximated by finite differences

of the gradients, are better. A key difference with quasi-Newton methods is that the Hessian approximation in those methods is usually positive definite, hence directions of negative curvature are not available. All the methods discussed may be applied to the case in which $H(x)$ is approximated by finite differences with little difficulty except for the need to compute the differences. The performance of such algorithms is almost indistinguishable, in most cases, from the case when an exact Hessian is used. Of course, the “exact” derivatives do themselves contain errors since they are computed in finite-precision arithmetic. There are not the same numerical issues in approximating second derivatives as there are to approximating first derivatives. It can be shown that when finite differences are used and the finite-difference interval does not converge to zero, which for numerical purposes it cannot, the quadratic rate of convergence is lost. However, this result is misleading. The iterates, except in pathological cases, mimic those of the exact case. Indeed the quadratic convergence of the exact cases also breaks down, but typically at the point the algorithm terminates.

When n is large, the number of differences could grow with n . When $H(x)$ (or $J(x)$ in the nonlinear eqnarray case) is a sparse matrix, there are clever algorithms that can choose the direction of the differences in a manner that significantly reduces the number of differences required [6]. For example, if $H(x)$ is tridiagonal, only two differences are required.

CONSTRAINED PROBLEMS

The general nonlinearly constrained problem may be stated as

$$\min_{x \in \mathbb{R}^n} f(x) \text{ such that } c(x) \geq 0, \quad (23)$$

where $c(x) \in \mathbb{R}^m$ is a vector of smooth functions. It is usual to distinguish linear from nonlinear constraints, and further, to distinguish simple bounds on the variables from linear constraints. Generally, equality constraints are easier to handle than inequality and for simplicity, are often

omitted. For problems with only linear constraints the iterates sequence generated is usually feasible and that has great benefits. Constraints complicate the adaptation of Newton’s method as does size and not surprisingly, large constrained problems are the most difficult of all. It is beyond the scope of this paper to consider all the issues in detail but we shall cover some of the salient issues.

Consider first a problem whose only constraints are simple equalities. By that we mean some subset of the variables are fixed at some value. Clearly, this creates no issues since the problem is unconstrained in the remaining variables. If there are simple inequalities then at each iteration an active-set method fixes some subset of the variables. Consequently, Newton-type methods using an active-set strategy are relatively easy to adapt to such problems. However, consider a trust-region method whose only constraints are $x \geq 0$. Adding the constraints $x_k + s_k \geq 0$ to the subproblem (20) makes the subproblem intractable. Typically the quadratic constraint is replaced by bounds on the step, which then gives a pure bounds constrained subproblem. However, finding the global minimizer of even this subproblem is intractable. It is still possible to find a step that reduces the objective. What is lost is that the modified algorithm is no longer assured of generating a sequence that converges to a point that satisfies the *second-order* necessary conditions.

As noted, for an active-set linesearch method, there are no complications for problems with simple bounds. There are also no complications with general linear constraints provided the problem is not too large. Issues do arise when the problem is large. These are not insurmountable but requires some ingenuity. When we have linear constraints that are active, we need to find a DNC that lies on the constraints or to put it another way, a DNC that is orthogonal to the constraint normals. We also need to modify the *reduced* Hessian rather than the Hessian. Suppose at the k th iteration we wish to remain on a set of constraints $A_k = b_k$. The subproblem we need to solve to obtain the Newton step is

$$\min_p \left\{ \frac{1}{2} p^T H_k p + g_k^T p \mid A_k p = 0 \right\}.$$

Let Z_k be a $n \times (n - m_k)$ full rank matrix such that $A_k Z_k = 0$, where m_k is the number of rows of A_k . We are assuming A_k is full rank. The solution to this problem is given by

$$Z_k^T H_k Z_k p = -Z_k^T g_k. \quad (24)$$

However, if $Z_k^T H_k Z_k$ is not positive definite, it needs to be modified in a manner similar to how H_k is modified in the unconstrained case. There is little difficulty in doing this when n is of modest size. There are not a lot of issues if $n - m_k$ is of modest size even if n is large, although forming the product may be expensive. Fortunately, H_k is typically sparse and an implicit form of Z_k may be found that is also sparse. In some cases, advantage can be made of structure both in A_k and H_k . However, there are cases where both n and $n - m_k$ are large and $Z_k^T H_k Z_k$ is not sparse. Under such circumstances, there are two approaches. One is to consider, instead of using the reduced system (24), solving the equivalent Karush-Kuhn-Tucker system

$$\begin{pmatrix} H_k & A_k \\ A_k^T & 0 \end{pmatrix} \begin{pmatrix} p_k \\ -\lambda_k \end{pmatrix} = \begin{pmatrix} -g_k \\ 0 \end{pmatrix}, \quad (25)$$

where λ_k is the Lagrange multiplier estimate. This matrix is indefinite regardless of the character of H_k . However, it may be deduced from the inertia of this matrix whether or not the reduced Hessian is positive definite. Factorizing this matrix in the form $PLBL^T P^T$, where P is a permutation matrix, L is a unit lower triangular matrix, and B is a 2×2 block-diagonal matrix reveals the inertia. Unfortunately, if the reduced Hessian is not positive definite, this factorization does not reveal how to obtain a suitable sufficient descent direction. How to obtain suitable descent directions by modifying this factorization is described in Forsgren and Murray [10]. They also suggest how to modify the original matrix prior to using an unmodified factorization.

An alternative to factorizations is to attempt to solve Equation (24) using the conjugate gradient (CG) method. Since the

CG algorithm requires only matrix-vector products, the reduced Hessian need not be formed explicitly. The CG method may fail on indefinite matrices, but it is precisely because it may fail that makes it useful. It can also be shown that when it fails, a direction of sufficient descent may be constructed from the partial solution. While it may not give a direction of sufficient negative curvature in general it will usually give a direction of at least zero curvature, which if need be, may be improved by using this as an initial vector in minimizing $d^T Z_k^T H_k Z_k d / d^T d$ either by a few iterations of the Lanczos algorithm or a few iterations of univariate search.

When there are nonlinear inequality constraints, then adapting Newton's method is considerably more problematic except if the nonlinear constrained problem is transformed into solving a sequence of linearly constrained problems. Assuming that is not the case, most methods generate infeasible iterates. As a consequence, the iterate is typically composed of two components: one is a Newton step to get feasible and the other to "reduce" (it may be increasing) the objective. If there are only equality constraints it is somewhat simpler, so we shall describe that first. We are now concerned not with the Hessian of the objective, but with the Hessian of the Lagrangian, where the Lagrangian $L(x, \lambda)$ is defined as $L(x, \lambda) \equiv f(x) - \lambda^T c(x)$. Assuming there are no issues with the reduced Hessian of the Lagrangian, the system of equations we need to solve are

$$g(x) - J(x)^T \lambda = 0 \text{ and } c(x) = 0, \quad (26)$$

which is a system of $n + m$ equations in $n + m$ unknowns. In other words, we are now applying Newton's method in both the primal and dual variables. The Newton step in these variables is given by

$$\begin{pmatrix} H_k^L & J_k \\ J_k^T & 0 \end{pmatrix} \begin{pmatrix} p_k \\ -\Delta \lambda_k \end{pmatrix} = \begin{pmatrix} -g_k + J_k^T \lambda_k \\ -c_k \end{pmatrix}, \quad (27)$$

where H_k^L is the Hessian of the Lagrangian at x_k, λ_k , and $\Delta \lambda_k$ is the Newton step in the

dual variables. The issues in addressing the case when the reduced Hessian is not positive definite in the space of the x -variables is similar to the linearly constrained case. We have no concern about the character of the Hessian in the space of the dual variables. However, since the search is in the space of both variables, there needs to be a search direction defined for those variables; the method is described in Murray and Prieto [11]. Note that we are leaving out the fact we are minimizing a merit function, so care needs to be taken to ensure directions of negative curvature for the Hessian of the Lagrangian are also directions of negative curvature for the merit function. Again, how this may be done is described in Murray and Prieto [11].

The issue with an active-set method for nonlinear constraints is that the most efficient approach is a sequential quadratic programming (SQP) method. Such methods construct a quadratic objective whose Hessian is an approximation to the Hessian of the Lagrangian. When second derivatives are known of both, the original objective and the of the nonlinear constraint functions, only the Lagrange multipliers need be estimated. If the quadratic programming (QP) is not convex, the solution of the QP is not necessarily a direction of sufficient descent. Indeed the QP may not have a bounded solution and even if it does, and the global minimizer is found, that may not yield a direction of descent. In solving the QP, the iterates move on to different sets of active constraints. It is possible for the reduced Hessian to be positive definite on every subspace and yet the solution is not a descent direction. Simply observing the character of the reduced Hessians may not reveal nonconvexity. Unlike the equality-constrained case, we do not know initially the null space of the active set of the constraints since we do not know which constraints are active at the solution of the QP. Moreover, altering the Hessian on that subspace will alter the set of constraints active at the solution. This conundrum may be resolved by monitoring the total step being taken in the QP from the initial feasible point. Assuming the initial reduced Hessian is positive definite (if it is not, the the Hessian may be

modified by applying the modified Cholesky factorization to the reduced Hessian), there are no problems provided only constraints are added. It is when a constraint is deleted that indefiniteness may arise. While it may not arise in the resulting reduced Hessian, the indefiniteness in the direction from the initial point must be checked. While the Hessian still has positive curvature along that direction, a descent direction is assured. When it does not, the situation is similar to that of applying the CG algorithm and it breaks down; the prior step is a descent direction and the new step yields a DNC.

Approximating second derivatives is sometimes cheaper for constrained problems, especially in the linearly constrained case. Since we only need to approximate $Z^T HZ$, then we can approximate HZ directly by differencing along the column vectors of Z . When $n - m$ is small, this is quite efficient. Also if the system (24) is solved using the CG algorithm we need only difference (this holds for the unconstrained case also) along the CG directions, which may be only a few before a sufficiently good search direction is obtained.

A Homotopy Approach

Rather than change the algorithm, another way to extend the range of convergence of Newton's method is to change the problem or rather replace the problem by a sequence of problems. For example, we can use a homotopy approach. The basic idea is to replace the original problem with a parameterized problem. At one end of the parameter range, the problem is easy to solve and at the other end, it is the original problem. Such an approach may be used for globally convergent algorithms also since it can be more efficient than simply solving the original problem directly. Here, our use is not because the problem is necessarily hard to solve but because Newton's method may not work at all. Note that when you do start close to the solution with Newton's method, the problem is usually easy to solve since the iterative sequence converges quickly.

Constructing a homotopy for the case of solving $f(x) = 0$ is particularly easy. Instead of solving $f(x) = 0$, we could solve

$f(x) = \gamma f(x_0)$, where x_0 is our initial estimate, and $0 \leq \gamma < 1$. Obviously if γ is very close to 1, then x_0 is very close to $x^*(\gamma)$, where $x^*(\gamma)$ is a zero of $f(x) = \gamma f(x_0)$. Since we can make γ as sufficiently close to 1 as we wish, we can be within the interval of convergence provided the gradient of $f'(x^*(\gamma)) \neq 0$. It is not necessary to find the solution to the intermediate problems precisely. The main difficulty is assessing how conservative to make the initial choice of γ and how quickly it can be reduced. In one variable, this approach makes the Newton step smaller and as such plays a similar role to α_k in Equation (8). However, note that it is not identical to a fixed scaling of the Newton step.

Another way of modifying functions is to make them more like the ideal case for Newton's method. When solving $f(x) = 0$, that can be done by adding a linear function, for example, solve $(1 - \gamma)f(x) + \gamma(x - x_0) = 0$. Here, we change the gradient of the function as well as move the zero closer to x_0 . A similar approach may be taken for the problem $\min_x f(x)$ by adding a quadratic function.

If at the initial estimate $f'_0 = 0$, then a different initial estimate is needed regardless of the approach being used to solve the problem.

It can be particularly useful to use a homotopy approach when using an SQP algorithm. As noted, when the Hessian is indefinite difficulties arise. Adding a term $\frac{1}{2}\rho(x - \bar{x})^T(x - \bar{x})$ to the objective, where $\bar{x}$ is the initial approximation, adds γI to the Hessian. Not only will this reduce the need to modify the Hessian, it also almost always reduces the number of iterations required to solve the QP subproblem. If γ was very large, then we would be taking a very small optimization step from the initial feasible point of the QP subproblem. It is advisable to change $\bar{x}$ periodically (perhaps even every iteration) and also to reduce γ to zero. When the iterates are close to the solution and the reduced Hessian of the Lagrangian is positive definite, then indefiniteness will not arise when solving the QP. Indeed, close to the solution, only one iteration of the QP is required since the correct active set has been identified. There is much more that could be written in particular on extensions of Newton's method to both,

preserve and improve upon the rate of convergence. It would also be remiss not to cite the classic work of Kantorovich [12].

Acknowledgments

Thanks are due to Nick Henderson for reading the manuscript and to the referees for their prompt reviews and insightful comments. Support for this work was provided by the Office of Naval Research (Grant: N00014-02-1-0076) and the army (Grant: W911NF-07-2-0027-1).

PARADIGM-PRESERVING VERSUS PARADIGM-SHIFTING THEORIES OF RATIONAL CHOICE

Let S be a partitioning of the possible states of the world and let D be a set of possible decisions whose outcomes depends upon which state s in S obtains. Define a decision d in D as a function, $d[s]$, mapping each state into an outcome.

Savage's seminal book, the *Foundations of Statistics*, considers an individual rational if and only if that individual's preferences over decisions in D satisfy seven consistency postulates [1]. Savage showed that such an individual chooses that decision d with the highest expected utility (EU) where EU is defined by

$$u(d) = \sum_{s \in S} p(s)u(d[s])$$

with $p(s)$ being a probability distribution defined over states s in S and with $u(d[s])$ being a utility function defined over the outcome of making decision d in state s . While Savage's theory is called (subjective) EU theory, it does not presume that rational individuals use probability or utility functions in making their decisions.

Several problems with Savage's EU theory were identified in the second half of the twentieth century. In the *Foundations of Statistics* (from which all quotations are drawn unless otherwise indicated), Savage conceded that

it is undoubtedly true that the behavior of people does often flagrantly depart from the theory (Section 5.6, p. 100–101)

but nonetheless felt that his theory still provided a solid guide to rational behavior. In addition, he noted that

many apparent exceptions to this theory can be interpreted as not to be exceptions at all. For example, a flier may be observed doing a stunt that risks his life, apparently for nothing. That seems to be in contradiction to the theory, but if, in addition, the flier is known to have a real and practical need to convince himself and his colleagues of his courage, then he is simply paying for advertising with the risk of his life, which is not in itself in contradiction to the theory (Section 5.6, p. 101).

Savage considered this creative reinterpretation useful and noted that

The law of the conservation of energy and matter owes its success largely to being an expression of remarkable and reliable facts of nature but to some extent also to certain conventions by which new sorts of energy are so defined as to keep the law true (Section 5.6, p. 101).

For example, in response to Aumann's objection to his axioms, Savage wrote

The difficulties that you mention are all there; I have known about them in a confused way for a long time The theory of personal probability and utility is, as I see it, a sort of framework into which I hope to fit a large class of decision problems. In this process, a certain amount of pushing, pulling and departure from commonsense may be acceptable and even advisable. . . . I believe and examples have confirmed that decision situations can be usefully structured in terms of consequences, states and acts in such a way that the postulates of the Foundations of Statistics are satisfied. Just how to do that seems to be an art for which I can give no useful prescription and for which it is perhaps unreasonable to expect one—as we know for other postulate systems for application. [Letter from Leonard Savage to

R. Aumann, 1971 reprinted in Dreze [2], p. 78–81.)]

But even though Savage did allow for some *departure from commonsense*, Savage recognized that if extreme departures were constantly required to make the theory work, the theory would have to be questioned. As he notes:

In general, the reinterpretation needed to reconcile various sorts of behavior with the utility theory is sometimes quite acceptable and sometimes so strained as to lay whoever proposes it open to the charge of trying to save the theory by rendering it tautological. The same sort of thing arises in connection with many theories and I think there is general agreement that there is no hard-and-fast rule to be laid down as to when it becomes appropriate to make the necessary reinterpretation (Section 5.6, p. 101).

To interpret Savage’s comments, consider Lakatos’s [3] definition of a research program as an evolving body of research based on certain core principles (in this case, Savage’s seven postulates), which remain unchanged while various auxiliary hypotheses are added to the research program to successfully address ever broader sets of problems and applications. This paper refers to these core principles as the paradigm and the addition of auxiliary hypotheses as paradigm-preserving since they enable the research program to address real problems without changing the underlying paradigm.

A research program becomes degenerative if the added hypotheses are ad hoc attempts to defend the paradigm against being falsified by empirical data which do not significantly expand the explanatory power of the research program. A degenerative research program is eventually supplanted by a more successful research program based on a different core/paradigm. We refer to efforts to develop the core of this rival research program as *paradigm-shifting*.

In discussing the various challenges to Savage’s axioms, we will similarly distinguish between

1. Paradigm-preserving research which adds auxiliary hypotheses or reframes

the problem situation so that Savage’s axioms apply and

2. Paradigm-shifting research which addresses the empirical challenges by relaxing or replacing some or all of Savage’s postulates.

This paper focuses on the postulates relaxed or eliminated by the well known non-EU models. As a result, this paper will not discuss Savage’s fourth, fifth, and seventh postulate, even though the fourth postulate was challenged by Shafer [4] and the seventh postulate was challenged by Seidenfeld and Schervish [5].

THE TRANSITIVITY AXIOM: SAVAGE’S FIRST POSTULATE

The transitivity axiom states that if apples are preferred to bananas and if bananas are preferred to cantaloupes then apples must be preferred to cantaloupes. While this condition is generally considered essential even in decision making without uncertainty, violations do occur. For example, experimental subjects tend to choose gambles which have a higher probability of yielding some moderate payoff over riskier gambles with a higher payoff while assigning those riskier gambles a higher monetary value [6]. This “preference” reversal effect is sometimes interpreted as an artifact of the experimental design so that it does not imply intransitive behavior. But Loomes and Sugden [7] and Loomes *et al.* [8] view these (and other) experiments as evidence for intransitivity and have proposed regret theory as an intransitive generalization of Savage’s model.

While Savage’s theory indicates that an individual is only concerned with the consequences of his decision, regret theory indicates that an individual may also be concerned about whether his decision will still be considered the “right” decision after the uncertainty about state s is resolved. Typical formalizations of regret theory specify a regret function r and write the regret utility function as

$$u(d) = \sum_{s \in S} p(s)[u(d[s]) + r[u(d[s]) - u(s)]],$$

so that the utility of a decision given state s is measured not only by its utility in state s but by how that utility compares to the utility that would have been obtained, $u(s)$, had some other decision occurred. In many cases, $u(s)$ is the utility that would have obtained if we had known that state s would occur (and could have made the optimal decision given s occurred). Since $u(s)$ will be a function of the decisions in the choice set, D , an individual's preference between two decisions d^* and d^{**} , might change if we changed the choice set D to a different choice set D^* (where both D and D^* include decisions d and d^*). This often leads to intransitive behavior.

A more general approach [9] defines the relative utility of a consequence $d[s]$ in state s given that consequence $d^*[s^*]$ occurred in state s^* with the skew-symmetric bilinear (SSB) function $W(d[s], d[s^*])$. In their SSB utility theory, the individual chooses d over d^* if the expected value of this function is positive, that is, if

$$\sum_{s \in S} p(s)p(s^*)W(d[s], d[s^*]) > 0.$$

In the paradigm-preserving version of regret theory, the utility of decision d in state s is defined over both the direct consequences of the decision $d[s]$ as well as the indirect consequence of knowing what other consequences might have been achieved with a different decision. Thus, instead of defining regret as a function of utility, the utility function is defined as a function of regret. For example, let $V(d)$ be a random variable describing the possibly uncertain outcomes of decision d . Suppose an individual is working for stakeholders who will only reward the manager if the individual makes the “right choice,” that is, if, out of a possible set of decisions D , the manager chooses that decision which—once the state s is known—provides the most desirable outcome.

Define the random variable T by $T = \text{Max}_{d \in D} V(d)$.

Then the individual will choose that decision d maximizing the probability of $X(d)$ not being less than T . This behavior is fully rational given the individual's incentives and can be incorporated in Savage's

paradigm by redefining the consequence of a decision to include both direct and indirect consequences. But if the stakeholders thought the set of possible decisions was described by the choice set D^* , then the individual might make a different choice. By appropriately varying the choice set D , the individual might then exhibit a set of preferences which seems to violate intransitivity. However, this apparent intransitivity is not inconsistent with Savage's postulates because it arises from real changes in the situation the individual confronts. Thus, the paradigm-preserving interpretation of regret theory avoids violating the transitivity axiom by making an additional assumption about the environment the individual confronts.

THE SURE-THING PRINCIPLE: SAVAGE'S SECOND POSTULATE

Most of the early challenges to Savage's axioms focus on Savage's Sure-Thing Principle. Consider the situation in which two decisions lead to the same set of consequences given event E . The Sure-Thing Principle then concludes that an individual's preference between these two decisions should only be determined by the events where the decisions lead to different consequences. In other words, the individual's preference between the two decisions is independent of the consequences that both decisions incur when event E occurs. Unfortunately, there is ample evidence of a *common-consequence* effect where an individual's preferences between two gambles does change when the *common-consequence* (which both decisions incur when an event E occurs) changes.

Allais [10] presented the first *common-consequence* challenge to the Sure-Thing Principle with an experiment offering individuals two choices. The first choice was between a sure chance of a million dollars (Gamble 1) and a gamble offering a large chance of winning a million dollars, a smaller chance of winning five million and a tiny chance of winning nothing (Gamble 2). The second choice was between two gambles, both of which were likely to yield nothing with one gamble, Gamble

4, offering a chance of five million dollars (vs one million dollars) at a slightly increased risk of winning nothing. As Savage explained,

Many people prefer Gamble 1 to Gamble 2 because, speaking qualitatively, they do not find the chance of winning a very large fortune in place of receiving a large fortune outright adequate compensation for even a small risk of being left in the status quo. Many of the same people prefer Gamble 4 to Gamble 3 because, qualitatively speaking, the chance of winning is nearly the same in both gambles, so the one with the much larger prize seems preferable (Section 5.6, p. 102).

For the specific probabilities used in the Allais Paradox, these choices violated Savage's utility theory. Savage acknowledged that

Examples like the one cited do have a strong intuitive appeal; even if you do not personally feel a tendency to prefer Gamble 1 to Gamble 2 and simultaneously Gamble 4 to Gamble 3, I think that a few trials with other prizes and probabilities will provide you with an example appropriate to yourself... When the two situations were first presented, I immediately expressed preference for Gamble 1 as opposed to Gamble 2 and Gamble 4 as opposed to Gamble 3 and I still feel an intuitive attraction to these preferences (Section 5.6, p. 103).

To overcome this intuitive attraction (which violated his axioms), Savage redefined the four lotteries as defining differing payoffs depending upon which one of three events occurred. Savage felt that this new representation made the folly of violating his axioms more transparent. In this new representation, Savage declared that

I prefer Gamble 1 to Gamble 2 and (contrary to my initial reaction), Gamble 3 to Gamble 4. It seems to me that in reversing my preference between Gamble 3 and Gamble 4, I have corrected an error (Section 5.6, p. 103).

Thus, Savage argues that his own psychological tendency to violate the Sure-Thing Principle in the Allais Paradox could be overcome by appropriately defining a small world

for the Allais Paradox where all gambles had a common support.

A multitude of experiments followed the original experiments by Allais and eventually led to some paradigm-shifting efforts to generalize the Sure-Thing Principle. Machina [11] described the results of these experiments using a Marschak triangle defined over a three-outcome lottery (which gives payoffs with utility 1, y , and 0 with probabilities p, q , and $1 - p - q$.) For utility theory, this lottery has a utility of $U = p + qy$. The indifference curve—defined by those values of p and q which lead to a lottery with utility U —is linear and parallel since $p = U - qy$. However, the experimental results suggest that the indifference curves exhibit a 'fanning out' effect.

To be consistent with this "fanning out" phenomenon, Chew [12] modified Savage's second postulate. This led to a theory where, for some function v , individuals would maximize the following weighted EU function:

$$\sum_{s \in S} p(s)v(d[s])u(d[s]) / \sum_{s \in S} p(s)v(d[s])$$

But Bordley and Hazen [13] showed that this weighted EU function was consistent with Savage's EU theory by making the auxiliary paradigm-preserving assumption of suspicious decision makers. Specifically, suppose the decision maker's subjective probability for state s was initially $p(s)$. The individual is then offered a lottery promising unusually high payoffs (or unusually costly penalties) if state s^* occurs. Since the individual thinks that their wealth is unlikely to change dramatically, the individual could conclude that the chances of s^* occurring are lower than they originally believed. As a result, the individual uses Bayes Rule to lower the initial assessed probability for s^* from $p(s^*)$ to

$$p^*(s^*) = p(s^*) \left[\frac{p(\text{Lottery is offered} | s^*)}{p(\text{Lottery is offered})} \right].$$

If we denote the likelihood function by $v(d[s])$, that is, if we define

$$v(d[s]) = \frac{p(\text{Lottery is offered} | s)}{p(\text{Lottery is offered})},$$

then Chew's weighted EU function is equivalent to Savage's EU theory with $p(s)$ replaced by $p^*(s)$ for each s in S .

Thus, Chew's paradigm-shifting weighted EU theory might be interpretable in a paradigm-preserving way as Savage's model coupled with the auxiliary hypothesis that individuals update their prior beliefs given the event of being offered a lottery. Similar assumptions can also be used to derive the intransitive SSB utility model from EU theory [14].

Another more dramatic modification to Savage's axiom was Machina's [15] approach which simply eliminated the Sure-Thing Principle. This led to a nonlinear EU model with nonlinear indifferent curves and the fanning out property. Machina also observed that a linear approximation of his generalized utility function at a given probability was interpretable as a local EU function that satisfied all the rationality axioms and was applicable to that family of gambles in the neighborhood of this probability distribution.

Harless and Camerer [16] reviewed thousands of empirical tests of Savage's EU theory (EU) versus these (and other) proposed models of how individuals choose. Since increasing the number of estimable parameters in a model often increases its fit without improving its predictiveness, they evaluated each model based on empirical fit and on number of estimable parameters. Their article noted that

There are dramatic differences between theory accuracy when the gambles in a pair have different supports and when they have the same support. EU predicts poorly when the support is different and predicts well when the support is the same . . . When lotteries have different supports, there is never a price-of-precision which justifies using EU. [16], p. 1280.

Now Savage had shown that his own tendency to be misled by the Allais Paradox was eliminated when gambles were defined across common supports. This experience is consistent with Harless and Camerer's [16] finding that EU theory is reasonably descriptive when gambles are defined over a common support. When lotteries have different support, their results favored Kahneman and

Tversky's [17] prospect theory, a psychological theory of choice that, unlike generalized EU, was not explicitly derived from a relaxation of Savage's axioms and was not intended as a normative theory.

In fact, Hammond [18] challenged the normative status of non-EU theories by arguing that an individual violating the Sure-Thing Principle could make a decision at the start of a multistage decision and then "change that decision" in later stages—even in the absence of new information. In response to this argument, non EU theorists argued that standard decision analytic approaches to addressing multistage decision problems were not necessarily appropriate with non EU theory. (Note, of course, that theories which attributed apparent violations of the Sure-Thing Principle to factors like suspicion would be dynamically consistent once the suspicion is taken into account.)

Savage's comments were not intended to suggest that the Sure-Thing Principle is only normatively applicable to gambles defined over the same support. But it does suggest the possibility of creating a non-EU theory which restricts the class of decisions to which the Sure-Thing Principle applies. Building on work by Quiggin [19], Schmeidler [20] developed such a theory. Define a lottery where the individual receives payoff x_i if a state included in event E_i occurs by the vector $(E_1, x_1, \dots, E_n, x_n)$ where events are ordered so that $x_1 > x_2 > \dots > x_n$. Define the probability weighting function

$$q_j = W(E_1 \text{ or } \dots \text{ or } E_j) - W(E_1 \text{ or } \dots \text{ or } E_{j-1})$$

Schmeidler's axioms showed that individuals maximize the Choquet EU [21]:

$$\sum_j q_j u(d[E_j])$$

The preference ordering of decisions implied by Choquet EU theory is consistent with Savage's EU theory when decisions are co-monotonic [22], i.e., when the lotteries describing the uncertainty associated with different decisions order events in the same way [23]. Since Choquet EU theory satisfies

stochastic dominance and transitivity, its proposed transformation of probabilities was used to create an updated version of prospect theory. The resulting cumulative prospect theory [23] remains one of the most popular psychological theories of individual choice.

Diecidue and Wakker [24] interpreted q_j as the individual's "probability" for event E_j adjusted by the individual's perception of the desirability of event E_j occurring. Thus q_j is, in some limited ways, analogous to Bordley and Hazen's paradigm-preserving suspicion-adjusted probabilities.

SEPARATION OF BELIEFS AND VALUES: SAVAGE'S THIRD POSTULATE

Savage viewed decisions as functions that, for each possible state of the world, s in S , led to some consequence. Utility functions, which expressed the individual's values, were defined over consequences while probabilities, which expressed the individual's beliefs, were defined over states. Savage's third postulate argued that if one consequence was preferred to another (e.g., if more money was preferred to less), than a decision that led to the first consequence—if we knew the state of the world was s —would be preferred to a decision that led to the second consequence (given state s). But Savage (Section 2.7, p. 25) noted that the reasonableness of this postulate

depends largely on the interpretation we choose to make of our technical terms, as an example helps to bring out. Before going on a picnic with friends, a person decides to buy a bathing suit or a tennis racket, not having at the moment enough money for both. If we call possession of the tennis racket and possession of the bathing suit consequences, then we must say that the consequences of his decision will be independent of where the picnic is actually held. If the person prefers the bathing suit, this decision would presumably be reversed if he learned that the picnic were not going to be held near water . . . But under the interpretation of 'act' and 'consequence' I am trying to formulate, this is not the correct analysis of the situation. The possession of the tennis racket and the possession of the bathing suit are to be regarded as acts, not consequences . . . The

consequences relevant to the decision are such as these: a refreshing swim with friends, sitting on a shadeless beach twiddling a brand-new tennis racket while one's friends swim, etc.

Thus, the plausibility of the third postulate is contingent on defining consequences in terms of the ultimate objects over which utility is defined. From a practitioner's perspective, this complicates the application of EU theory. It becomes especially difficult in medical decision making where decisions can physically change the individual's ability to enjoy certain consequences. To avoid overly contrived definitions of consequence, Schervish *et al.* [25] and Karni [26] articulated a theory of state-dependent consequences where both probability and utility now depend on states. This can make independently eliciting probabilities and utilities more difficult than in Savage's original formalism.

Now in the history of physics, an alternate formally equivalent representation of Newtonian mechanics, known as *Hamiltonian mechanics*, emerged and was found to be easier to use than Newtonian mechanics in certain applications. Furthermore, quantum mechanics—a paradigm-shifting generalization of Newtonian mechanics—was more easily understood as a generalization of Hamiltonian mechanics than as a generalization of Newtonian mechanics. We now introduce an alternate (and formally equivalent) representation of EU known as *target-oriented utility theory* which likewise makes certain generalizations of EU easier to understand.

For convenience, suppose there is some performance metric v such that the utility of $d[s]$ can be written as some strictly monotonic function of $v(d[s])$. (Using this function v is purely a convenience which is not essential to target-oriented utility theory.) Since Fishburn [27] established that the utility function must be bounded, the utility of $d[s]$ can always be written as the probability that $v(d[s])$ exceeds T for some random variable T . Suppose $V(d)$ is a random variable with the probability of $V(d)$ exceeding v being the probability that decision d leads to an outcome $d[s]$ with $v(d[s]) > v$. Then, target-oriented

utility theory [28–30] writes the EU of decision d as the probability that $V(d)$ exceeds T where T must be uncorrelated with $V(d)$ for all d in D .

Relaxing the assumption of $V(d)$ and T being correlated leads to state-dependent EU theory. Savage had claimed that redefinition of consequences can eliminate state-dependence. To provide an example of where this claim is true, suppose there are random background influences W (e.g., changes in the value of the dollar) that affect both $V(d)$ and T . If there exist uncorrelated random variables $V^*(d)$ and T^* such that $V(d)$ and T are strictly monotonic functions of $V^*(d) + W$ and $T^* + W$, then $u(d)$ can easily be written as the probability that $V^*(d)$ exceeds T^* , that is, as a state-independent EU model. Unfortunately, this transformation only eliminates the simplest cases of state-dependence and hence does not show how state-dependence can be more generally eliminated.

To address violations of the Sure-Thing Principle and transitivity, Becker and Sarin [31] introduced their paradigm-shifting lottery-dependent utility theory. In this model, the EU of a lottery is

$$\sum_{s \in S} p(s)u(d[s], z) \text{ where } z = \sum_{s \in S} p(s)h(d[s])$$

The model states that the individual's EU is a multiattribute utility with two attributes—one determined by the direct consequences of the decision and the other determined by a statistic describing the gamble from which the individual received this consequence. But Castagnoli and LiCalzi [32] and Modesti [33] showed that this model can be reinterpreted as a paradigm-shifting generalization of target-oriented utility theory where T varies with the set of decisions the individual is evaluating.

Oden and Lopes [34] introduced S/A (security/aspiration level) theory where individuals have an uncertain security threshold on what is minimally acceptable and an uncertain threshold on the maximum they aspire to achieve. This is closely related to target-oriented utility theory with an

appropriately chosen random variable T . Oden and Lopes's theory generalizes target-oriented utility theory in a paradigm-shifting way by allowing these thresholds to vary depending upon how a problem is presented. In a series of experiments, Oden and Lopes argued that their theory was as predictively valid as cumulative prospect theory.

But target-oriented utility theory can be viewed as a generalization of Simon's [35] model of the satisfying individual who only tries to meet fixed targets. This generalization is directly applicable to goal-oriented decision makers

1. who are uncertain of what their goals are, or
2. who know their goals but are uncertain about what outcomes are required to achieve their goal.

In this second case, T represents the uncertain requirements for achieving the goal. Examples of such goals include the following:

1. the goal of exceeding the uncertain future performance of a competitor [36];
2. the goal of satisfying uncertain customer expectations [37];
3. a collective goal whose achievement depends on both the decision maker and the uncertain efforts of other team members [38];
4. the Hippocratic goal of making the patient healthier than the patient would be in the absence of medical treatment [39].

From the perspective of target-oriented utility theory, Savage's postulates imply that any rational individual acts like a goal-oriented individual who is uncertain about the requirements for achieving the goal. For certain purposes, this is a more transparent way to think about EU theory.

THE ARCHIMEDEAN AXIOM: SAVAGE'S SIXTH POSTULATE

Fishburn and LaValle [40] felt that Savage's Archimedean axiom was

the only axiom that can be violated in a prescriptively unassailable fashion.

For example, the axiom indicates that an individual should always be willing to take some possibly very small risk of the worst possible outcome for the sake of a modest gain. Hence, if a gamble had a small enough probability of annihilating the human race, an individual should be willing to accept the gamble for the sake of a modest increase in wealth. But Pascal [41] advocated rejecting any decision with even the slightest possibility of an ‘infinitely’ bad outcome.

One paradigm-preserving resolution of this problem presumes that the decision analyst defines the set of possible decisions D to exclude decisions with potential outcomes that are “infinitely worse” than the outcomes of other available decisions. In other words, the decision analyst will not even consider illegal or morally reprehensible decisions. A paradigm-shifting resolution of this problem is Fishburn and LaValle’s [40] lexicographic EU theory which replaces Savage’s scalar-valued EU theory with a theory of vector-valued utilities and matrix-valued probabilities.

But there is another problem with Savage’s sixth postulate—its assumption that any state could be partitioned indefinitely into some grand world in which all distinctions possible have been made in extreme detail. After explicitly noting that this notion of a grand world is *preposterous* and *ridiculous*, Savage writes

any claim to realism about this book . . . or indeed by almost any theory of individual decision making I know . . . is predicated on the idea that some of the individual decision situations into which actual people tend to subdivide the grand world do recapitulate in microcosm the mechanism of the idealized grand world decision . . . The general method of attack I propose to follow, for want of a better one, is to talk in terms of the grand situation . . . tongue in cheek—and in those terms to analyze and discuss isolated decision situations (Section 5.5, p. 83).

Savage will discuss these isolated decision situations by introducing the concept of a small world whose states

are, in fact, events in the grand world, that indeed they constitute a partition of the grand world [and] a restricted set of grand world acts, regarded as small world consequences . . . a small world is complete satisfactory . . . if and only if it satisfies the seven postulates (Section 5.5, p. 84–86).

The small world is called a microcosm if the probability (and utility) in the small world is consistent with the probability and utility in the grand world:

If the small world satisfies the postulates but does not necessarily have a probability or utility consistent with the grand world, call it a pseudo-microcosm (Section 5.5, p. 86).

Savage argues that if the grand world satisfies his axioms, then any small world

can without difficulty be expanded into a somewhat larger small world that is a pseudo-microcosm [which] constitute a Boolean subalgebra of the Boolean algebra of the grand world events (Section 5.5, p. 88).

But, whenever there is a correlation between the uncertainties in two different small worlds, a better than expected (or worse than expected) outcome in one small world could lead to an adjustment in the small world EU which is inconsistent with small world EU maximization [42]. Hence, expanding a small world into a pseudo-microcosm requires some special care. But even if we can successfully construct such pseudo-microcosms, Savage noted that

A pseudo-microcosm is, however, completely satisfactory only if it is actually a microcosm, i.e., leads to a probability measure and a utility well-articulated with those of the grand world (Section 5.5, p. 88).

But how do we know when a pseudo-microcosm is a microcosm? Savage concedes that

Unfortunately the condition . . . is not also automatic. The general condition that a pseudo-microcosm be a microcosm . . . seems incapable of verification without taking the grand world much too seriously (Section 5.5, p. 90).

This raises the possibility, as Shafer noted, that probabilities

calculated in a small world that did satisfy his postulates might change with refinement. If the probabilities are different for two different levels of refinement, then which level is right? (Shafer, p. 384).

But Savage hypothesized that this issue was not a problem in practice, i.e., that individuals could easily determine the right probability and level of refinement:

I feel, if I may be allowed to say so, that the possibility of being taken in by a pseudo-microcosm that is not a real microcosm is remote, but the difficulty I find in defining an operationally applicable criterion is, to say the least, grounds for caution. (Savage 5.5, p. 90).

Unfortunately, empirical data shows that the assessed probabilities for events do vary with the degree of refinement in those events [43–51], even when experienced decision analysts make the assessments [52]. Hence, distinguishing between a microcosm and a pseudo-microcosm is not trivial. As a result

A subjective EU analysis of a decision problem using one small world may fail to give the same results as an analysis using a more detailed small world (Shafer, p. 480).

It is also possible that this problem may not be solvable. Since a state in Savage's grand world could include

The exact and entire present, past and future history of the world understood in any sense, however wide (Section 2.3, p. 8).

Savage's notion of a grand world, taken literally, conflicts with the Heisenberg Uncertainty Principle which rules out the possibility of defining the exact position and momentum of a quantum mechanical particle. While Savage only proposed discussing the grand world *tongue-in-cheek*, Von Neumann's [53] seminal book, the *Mathematical Foundations of Quantum Mechanics*, rules out the meaningfulness of even a *tongue-in-cheek* discussion of the

exact position and momentum of a quantum mechanical particle.

This theoretical issue does have serious practical implications. Specifically, quantum mechanics—while allowing well-defined probabilities over the observable outcomes of a specific experiment (a small world)—defines a complex probability amplitude describing the uncertainty associated with the grand world. Since a complex probability amplitude corresponds to a square two-dimensional matrix (differing from Fishburn and LaValle's matrix-valued probabilities), the probabilities in the small world cannot agree with the matrix-valued probability in the grand world. Hence, microcosms may not exist.

Despite this inconsistency between Savage and von Neumann, much of Savage's work was based on von Neumann and Morgenstern's [54] treatment of decision making with known probabilities:

the treatment of utility as applied to gambles . . . is virtually copied from their book. Indeed their ideas on this subject are responsible for almost all my own. (Section 5.6, p. 97).

The inconsistency arises from Savage's intentionally replacing von Neumann and Morgenstern's known probabilities with DeFinetti's [55] subjective probabilities. DeFinetti long recognized the apparent contradiction between subjectivist theories of probability and von Neumann's theory of quantum probability [56]. But resolving this contradiction would still be of only theoretical interest if these quantum mechanical effects did not arise in the macroscopic work of decision making.

But according to Von Neumann's quantum logic [57], the incompatibility between different quantum mechanical representations of a problem suggests that there is a similar incompatibility between different representations of problems in the social sciences. This hypothesis is supported by empirical studies in the emerging field of quantum cognition [58–63]; and a more recent special issue of the *Journal of Mathematical Psychology* (2009).

SUMMARY

The focus of this review has been on the tension between

1. efforts to address the limitations of EU theory by preserving the paradigm with creative problem definition, target-oriented reformulations of utility theory, auxiliary hypothesis like suspicion etc., and
2. efforts to address these limitations by shifting the paradigm.

The resolution of this debate between paradigm-preserving and paradigm-shifting approaches will ultimately depend upon which approach provides the most insight and convenience in practical decision making [64, 65].

To better focus on this debate, this review has bypassed many important developments in nonEU [66–68] as well as related work showing how Savage's axioms could be simplified by postulating the existence of randomizing devices [69].

INTRODUCTION

Conjugate gradient methods are a class of important methods for solving unconstrained optimization problems

$$\min f(x), \quad x \in R^n, \quad (1)$$

especially if the dimension n is large. They are of the form

$$x_{k+1} = x_k + \alpha_k d_k, \quad (2)$$

where α_k is a stepsize obtained by a line search, and d_k is the search direction defined by

$$d_k = \begin{cases} -g_k, & \text{for } k = 1; \\ -g_k + \beta_k d_{k-1}, & \text{for } k \geq 2, \end{cases} \quad (3)$$

where β_k is a parameter, and g_k denotes $\nabla f(x_k)$.

It is known from Equations (2) and (3) that only the stepsize α_k and the parameter β_k remain to be determined in the definition of conjugate gradient methods. In the case that f is a convex quadratic, the choice of β_k should be such that the methods (2) and (3) reduces to the *linear* conjugate gradient method if the line search is exact, namely,

$$\alpha_k = \arg \min \{f(x_k + \alpha d_k); \alpha > 0\}. \quad (4)$$

For nonlinear functions, however, different formulae for the parameter β_k result in different conjugate gradient methods and their properties can be significantly different. To differentiate the *linear* conjugate gradient method, sometimes we call the conjugate gradient method for unconstrained optimization as *nonlinear* conjugate gradient method. Meanwhile, the parameter β_k is called *conjugate gradient parameter*.

The linear conjugate gradient method can be dated back to a seminal paper by Hestenes and Stiefel [1] in 1952 for solving a symmetric positive definite linear system $Ax = b$, where $A \in R^{n \times n}$ and $b \in R^n$. An easy and geometrical interpretation of the linear conjugate gradient method can be founded in Shewchuk [2]. The equivalence of the linear system to the minimization problem of $\frac{1}{2}x^T Ax - b^T x$ motivated Fletcher and Reeves [3] to extend the linear conjugate gradient method for nonlinear optimization. This work of Fletcher and Reeves in 1964 not only opened the door to the nonlinear conjugate gradient field but greatly stimulated the study of nonlinear optimization. In general, the nonlinear conjugate gradient method without restarts is only linearly convergent [4], while n -step quadratic convergence rate can be established if the method is restarted along the negative gradient every n -step [5,6]. Some recent reviews on nonlinear conjugate gradient methods can be found in Hager and Zhang [7], Nazareth [8,9], and Nocedal [10,11]. This article aims to provide a perspective view on the methods from the angle of descent property and global convergence.

Since exact line search is usually expensive and impractical, the strong Wolfe line search is often considered in the implementation of nonlinear conjugate gradient methods. It aims to find a stepsize satisfying the strong Wolfe conditions

$$f(x_k + \alpha_k d_k) - f(x_k) \leq \rho \alpha_k g_k^T d_k, \quad (5)$$

$$|g(x_k + \alpha_k d_k)^T d_k| \leq -\sigma g_k^T d_k, \quad (6)$$

where $0 < \rho < \sigma < 1$. The strong Wolfe line search is often regarded as a suitable extension of the exact line search since it reduces to the latter if σ is equal to zero. In practical computations, a typical choice for σ that controls the inexactness of the line search is $\sigma = 0.1$.

On the other hand, for a general nonlinear function, one may be satisfied with a step-size satisfying the standard Wolfe conditions, namely, Equation (5) and

$$g(x_k + \alpha_k d_k)^T d_k \geq \sigma g_k^T d_k, \quad (7)$$

where again $0 < \rho < \sigma < 1$. As is well known, the standard Wolfe line search is normally used in the implementation of quasi-Newton methods, another important class of methods for unconstrained optimization. The work of Dai and Yuan [12,13] indicates that the use of standard Wolfe line searches is possible in the nonlinear conjugate gradient field. Besides this, there are quite a few Refs 14,15,16,17 that deal with Armijo-type line searches.

A requirement for an optimization method to use the above line searches is that, the search direction d_k must have the descent property, namely,

$$g_k^T d_k < 0. \quad (8)$$

For conjugate gradient methods, by multiplying Equation (3) with g_k^T , we have

$$g_k^T d_k = -\|g_k\|^2 + \beta_k g_k^T d_{k-1}. \quad (9)$$

Thus if the line search is exact, we have $g_k^T d_k = -\|g_k\|^2$ since $g_k^T d_{k-1} = 0$. Consequently, d_k is descent provided $g_k \neq 0$. However, this may not be true in case of inexact line searches for early conjugate gradient methods. A simple restart with $d_k = -g_k$ may remedy these bad situations, but will probably degrade the numerical performance since the second-derivative information along the previous direction d_{k-1} is discarded [18]. Assume that no restarts are used. In this article we say that, a conjugate gradient method is *descent* if Equation (8) holds for all k , and is *sufficient descent* if the sufficient descent condition

$$g_k^T d_k \leq -c \|g_k\|^2, \quad (10)$$

holds for all k and some constant $c > 0$. However, we have to point out that the borderlines between these conjugate gradient methods are not strict (see the discussion at the beginning of the section titled “Sufficient Descent Conjugate Gradient Methods”).

This survey is organized in the following way. In the next section, we will address two general convergence theorems for the methods of the form (2) and (3) assuming the descent property of each search direction. Afterwards, we divide conjugate gradient methods into three categories: early conjugate gradient methods, descent conjugate gradient methods, and sufficient descent conjugate gradient methods. They will be discussed in sections titled “Early Conjugate Gradient Methods”, “Descent Conjugate Gradient Methods”, and “Sufficient Descent Conjugate Gradient Methods”, respectively, with the emphases on the Fletcher–Reeves (FR) method, the Polak–Ribière–Polyak (PRP) method, the Hestenes–Stiefel (HS) method, the Dai–Yuan method, and the CG_DESCENT method by Hager and Zhang. Some research issues on conjugate gradient methods are mentioned in the last section.

GENERAL CONVERGENCE THEOREMS

In this section, we give two global convergence theorems for any methods of the form (2) and (3) assuming the descent condition (8) for all k . The first one deals with the strong Wolfe line search, while the second treats the standard Wolfe line search.

At first, we give the following basic assumptions on the objective function. Throughout this article, the symbol $\|\cdot\|$ denotes the two norm.

Assumption 1. (i) The level set $\mathcal{L} = \{x \in R^n : f(x) \leq f(x_1)\}$ is bounded, where x_1 is the starting point; (ii) in some neighborhood $\mathcal{N}$ of $\mathcal{L}$, f is continuously differentiable, and its gradient is Lipschitz continuous; namely, there exists a constant $L > 0$ such that

$$\|g(x) - g(y)\| \leq L \|x - y\|, \quad \text{for all } x, y \in \mathcal{N}. \quad (11)$$

Sometimes, the boundedness assumption for $\mathcal{L}$ in item (i) is unnecessary and we only require that f is bounded below in $\mathcal{L}$. However, we will just use Assumption 1 for the convergence results in this survey. Under Assumption 1 on f , we state a very useful result, which was obtained by Zoutendijk [19] and Wolfe [20,21]. The relation (12) is usually called as the *Zoutendijk condition*.

Lemma 1. *Suppose that Assumption 1 holds. Consider any iterative method of the form (2), where d_k satisfies $g_k^T d_k < 0$ and α_k is obtained by the standard Wolfe line search. Then we have that*

$$\sum_{k=1}^{\infty} \frac{(g_k^T d_k)^2}{\|d_k\|^2} < +\infty. \quad (12)$$

To simplify the statements of the following results, we assume that $g_k \neq 0$, for all k , for otherwise a stationary point has been found. Assume also that $\beta_k \neq 0$, for all k . This is because if $\beta_k = 0$, the direction in Equation (3) reduces to the negative gradient direction. Thus, either the method converges globally if $\beta_k = 0$ for infinite number of k , or one can take some x_k as the new initial point. In addition, we say that a method is *globally convergent* if

$$\liminf_{k \rightarrow \infty} \|g_k\| = 0, \quad (13)$$

and is *strongly convergent* if

$$\lim_{k \rightarrow \infty} \|g_k\| = 0. \quad (14)$$

If the iterations $\{x_k\}$ stay in a bounded region, Equation (13) means that there exists at least one cluster point, which is a stationary point of f , while Equation (14) indicates that every cluster point of $\{x_k\}$ will be a stationary point of f .

To analyze the methods of the form (2) and (3), besides Equation (9), we derive another basic relation. By Equation (3), we have $d_k + g_k = \beta_k d_{k-1}$ for all $k \geq 2$. Squaring both sides of this relation yields

$$\|d_k\|^2 = -2g_k^T d_k - \|g_k\|^2 + \beta_k^2 \|d_{k-1}\|^2. \quad (15)$$

The following theorem gives a general convergence result for any descent methods of the form (2) and (3) under the strong Wolfe line search. It indicates that, if $\|d_k\|^2$ is at most linearly increasing, namely, $\|d_k\|^2 \leq c_1 k + c_2$, for all k , a descent conjugate gradient method with strong Wolfe line search is globally convergent.

Theorem 1 [22]. *Suppose that Assumption 1 holds. Consider some methods of the form (2) and (3) with d_k satisfying $g_k^T d_k < 0$ and with the strong Wolfe line search (5) and (6). Then the method is globally convergent if*

$$\sum_{k \geq 1} \frac{1}{\|d_k\|^2} = +\infty. \quad (16)$$

Proof. It follows from Equations (9) and (6) that $|g_k^T d_k| + \sigma |\beta_k| |g_{k-1}^T d_{k-1}| \geq \|g_k\|^2$, which with the Cauchy–Schwarz inequality gives

$$(g_k^T d_k)^2 + \beta_k^2 (g_{k-1}^T d_{k-1})^2 \geq c_1 \|g_k\|^4, \quad (17)$$

where $c_1 = (1 + \sigma^2)^{-1}$ is constant. By Equation (15), $g_k^T d_k < 0$ and Equation (17), we have

$$\begin{aligned} & \frac{(g_k^T d_k)^2}{\|d_k\|^2} + \frac{(g_{k-1}^T d_{k-1})^2}{\|d_{k-1}\|^2} \\ &= \frac{1}{\|d_k\|^2} \left[(g_k^T d_k)^2 + \frac{\|d_k\|^2}{\|d_{k-1}\|^2} (g_{k-1}^T d_{k-1})^2 \right] \\ &\geq \frac{1}{\|d_k\|^2} \left[(g_k^T d_k)^2 + \beta_k^2 (g_{k-1}^T d_{k-1})^2 \right. \\ &\quad \left. - \frac{(g_{k-1}^T d_{k-1})^2}{\|d_{k-1}\|^2} \|g_k\|^2 \right] \\ &\geq \frac{1}{\|d_k\|^2} \left[c_1 \|g_k\|^4 - \frac{(g_{k-1}^T d_{k-1})^2}{\|d_{k-1}\|^2} \|g_k\|^2 \right]. \end{aligned} \quad (18)$$

Assume that Equation (13) is false and there exists some constant $\gamma > 0$ such that

$$\|g_k\| \geq \gamma, \text{ for all } k \geq 1. \quad (19)$$

Notice that the Zoutendijk condition (12) implies that $g_k^T d_k / \|d_k\|$ tends to zero. By this,

Equations (18) and (19), we have for sufficiently large k ,

$$\frac{(g_k^T d_k)^2}{\|d_k\|^2} + \frac{(g_{k-1}^T d_{k-1})^2}{\|d_{k-1}\|^2} \geq \frac{c_1}{2} \frac{\|g_k\|^2}{\|d_k\|^2}. \quad (20)$$

Thus, by the Zoutendijk condition and Equation (19), we must have that

$$\sum_{k \geq 1} \frac{1}{\|d_k\|^2} \leq \frac{1}{\gamma^2} \sum_{k \geq 1} \frac{\|g_k\|^2}{\|d_k\|^2} < +\infty, \quad (21)$$

which is a contradiction to the assumption (16). Therefore, we must have that the convergence relation (13) holds.

We are now going to provide another general global convergence theorem for any descent methods (2) and (3) with the standard Wolfe line search. To this aim, we define

$$t_k = \frac{\|d_k\|^2}{\phi_k^2}, \quad \phi_k = \begin{cases} \|g_1\|^2, & \text{for } k=1; \\ \prod_{j=2}^k \beta_j^2, & \text{for } k \geq 2. \end{cases} \quad (22)$$

By dividing Equation (15) by ϕ_k^2 and noticing that $d_1 = -g_1$, we can obtain [23] that for all $k \geq 1$

$$t_k = -2 \sum_{i=1}^k \frac{g_i^T d_i}{\phi_i^2} - \sum_{i=1}^k \frac{\|g_i\|^2}{\phi_i^2}. \quad (23)$$

Theorem 2 [17]. *Suppose that Assumption 1 holds. Consider any methods of the form (2) and (3) with d_k satisfying $g_k^T d_k < 0$ and with the standard Wolfe line search (5) and (7). Then the method is globally convergent if the scalar β_k is such that*

$$\sum_{k \geq 1} \prod_{j=2}^k \beta_j^{-2} = +\infty. \quad (24)$$

Proof. Define ϕ_k as in Equation (22). The condition (24) is equivalent to

$$\sum_{k \geq 1} \frac{1}{\phi_k^2} = +\infty. \quad (25)$$

Noting that $-2g_i^T d_i - \|g_i\|^2 \leq (g_i^T d_i)^2 / \|g_i\|^2$, it follows from Equation (23) that

$$t_k \leq \sum_{i=1}^k \frac{(g_i^T d_i)^2}{\|g_i\|^2 \phi_i^2}. \quad (26)$$

Since $t_k \geq 0$, the relation (23) also gives

$$-2 \sum_{i=1}^k \frac{g_i^T d_i}{\phi_i^2} \geq \sum_{i=1}^k \frac{\|g_i\|^2}{\phi_i^2}. \quad (27)$$

Noting that $-4g_i^T d_i - \|g_i\|^2 \leq 4(g_i^T d_i)^2 / \|g_i\|^2$, we get by this and Equation (27) that

$$\begin{aligned} 4 \sum_{i=1}^k \frac{(g_i^T d_i)^2}{\|g_i\|^2 \phi_i^2} &\geq -4 \sum_{i=1}^k \frac{g_i^T d_i}{\phi_i^2} - \sum_{i=1}^k \frac{\|g_i\|^2}{\phi_i^2} \\ &\geq \sum_{i=1}^k \frac{\|g_i\|^2}{\phi_i^2}. \end{aligned} \quad (28)$$

Now we proceed by contradiction and assume that Equation (19) holds. Then by Equations (28), (25), and (19), we have that

$$\sum_{k \geq 1} \frac{(g_k^T d_k)^2}{\|g_k\|^2 \phi_k^2} \geq \frac{\gamma^2}{4} \sum_{k \geq 1} \frac{1}{\phi_k^2} = +\infty, \quad (29)$$

which means that the sum series in the right-hand side of Equation (26) is divergent. By Lemma 6 in Pu and Yu [24], we then know that

$$\begin{aligned} +\infty &= \sum_{k \geq 1} \frac{(g_k^T d_k)^2}{\|g_k\|^2 \phi_k^2} \frac{1}{t_k} = \sum_{k \geq 1} \frac{(g_k^T d_k)^2}{\|g_k\|^2 \|d_k\|^2} \\ &\leq \frac{1}{\gamma^2} \sum_{k \geq 1} \frac{(g_k^T d_k)^2}{\|d_k\|^2}, \end{aligned} \quad (30)$$

which contradicts the Zoutendijk condition (12). The contradiction shows the truth of Equation (13).

Theorem 2 provides a condition on β_k , which is sufficient for the global convergence of a conjugate gradient method using the standard Wolfe line search. Instead of the sufficient descent condition (10), only the descent condition $d_k^T g_k < 0$ is used here. An easy understanding between Theorems 1

and 2 is given in Dai [23] under the strong Wolfe line search, in which situation we have the estimate $d_k \approx \beta_k d_{k-1}$, if there is no convergence. Since different nonlinear conjugate gradient methods only vary with the scalar β_k , we believe that the condition (24) in Theorem 2 is very powerful in the convergence analysis of conjugate gradient methods. See Dai [23] for some further uses of Equation (24).

EARLY CONJUGATE GRADIENT METHODS

The Fletcher–Reeves Method

In 1964, Fletcher and Reeves [3] proposed the first nonlinear conjugate gradient method and used the following conjugate gradient parameter

$$\beta_k^{\text{FR}} = \frac{\|g_k\|^2}{\|g_{k-1}\|^2}. \quad (31)$$

The introduction of the FR method is a milestone in the field of large-scale nonlinear optimization.

Early analysis with the FR method is based on the exact line search. Zoutendijk [19] proved that the FR method with line search is globally convergent for nonlinear functions. Al-Baali [25] first analyzed the FR method with strong Wolfe inexact line searches (5) and (6). He showed that if $\sigma < 1/2$, the sufficient condition (10) holds and there is global convergence. Liu *et al.* [26] extended Al-Baali's result to the case that $\sigma = 1/2$. Dai and Yuan [27] presented a simpler proof to this result by showing that the sufficient condition (10) holds for at least one of any two neighboring iterations. Here it is worth noting that after the descent condition (8) has been verified, we can establish the global convergence easily by Theorem 2. More exactly, assuming that there is no convergence and Equation (19) holds, we can see that $\prod_{j=2}^k \beta_j^2$ is at most linearly increasing and hence Equation (24) holds. Consequently, there will be global convergence by Theorem 2, leading to a contradiction.

Further, if $\sigma > 1/2$, Dai and Yuan [27] proved that even for the one-dimensional

quadratic function

$$f(x) = \frac{1}{2}x^2, \quad x \in R,$$

the FR method may fail due to generating an uphill search direction. Interestingly enough, if we continue the FR method by searching its opposite direction once an uphill direction is generated and keeping $x_{k+1} = x_k$ if g_{k+1} is orthogonal to d_{k+1} , it is still possible to establish the global convergence of the method. Dai and Yuan [28] considered this idea and showed the global convergence of the FR method under a generalized Wolfe line search.

Powell [18] analyzed the global efficiency of the FR method with the exact line search. Denote by θ_k , the angle between d_k and $-g_k$. The exact line search implies that g_{k+1} is orthogonal to d_k for all k and hence

$$\|d_{k+1}\| = \sec \theta_k \|g_k\| \quad (32)$$

and

$$\beta_{k+1} \|d_k\| = \tan \theta_k \|g_{k+1}\|. \quad (33)$$

By using the above two relations and substituting the formula (31), we can obtain

$$\tan \theta_{k+1} = \sec \theta_k \|g_{k+1}\| / \|g_k\| > \tan \theta_k \|g_{k+1}\| / \|g_k\|. \quad (34)$$

Now, if θ_k is close to $\frac{1}{2}\pi$, the iteration may take a very small step, in which case both the step $s_k = x_{k+1} - x_k$ and the change $y_k = g_{k+1} - g_k$ are small. Thus the ratio $\|g_{k+1}\| / \|g_k\|$ is close to one. Consequently, by Equation (34), θ_{k+1} is close to $\frac{1}{2}\pi$, which indicates that slow progress may occur again on the next iteration. The drawback that the FR method may fall into some circle of tiny steps was extended by Gilbert and Nocedal [29] to the strong Wolfe line search, and was observed by many researchers in the community. It explains why the FR method is sometimes very slow in practical computations.

Suppose that after some iterations, the FR method enters a region in the space of the

variables where f is the quadratic function

$$f(x) = \frac{1}{2}x^T x, \quad x \in R^n. \quad (35)$$

In this case, the exact line search along d_k and $g_k = x_k$ implies that

$$\|g_{k+1}\| = \|g_k\| \sin \theta_k. \quad (36)$$

By this and the equality in (34), we obtain $\theta_{k+1} = \theta_k$. Thus the angle between the search direction and the steepest descent direction remains constant for all consecutive iterations, which makes the method very slow if θ_k is close to $\frac{1}{2}\pi$. This example was addressed by Powell [18] for the two-dimensional case and is actually valid for any dimension.

As will be seen in the section titled “The Polak–Ribière–Polyak Method”, unlike the FR method, the PRP method can generate a search direction close to the steepest descent direction once a small step occurs and hence can avoid cycles of tiny steps. On the other hand, the PRP method need not converge even with the exact line search. This motivated Touati-Ahmed and Storey [30] to extend Al-Baali’s convergence result on the FR method to the general methods (2) and (3) with

$$\beta_k \in [0, \beta_k^{\text{FR}}] \quad (37)$$

and suggested the formula

$$\beta_k^{\text{TS}} = \max \left\{ 0, \min \left\{ \beta_k^{\text{PRP}}, \beta_k^{\text{FR}} \right\} \right\}. \quad (38)$$

Gilbert and Nocedal [29] further extended Equation (37) to the interval

$$\beta_k \in [-\beta_k^{\text{FR}}, \beta_k^{\text{FR}}] \quad (39)$$

and proposed the formula

$$\beta_k^{\text{GN}} = \max \left\{ -\beta_k^{\text{FR}}, \min \left\{ \beta_k^{\text{PRP}}, \beta_k^{\text{FR}} \right\} \right\}. \quad (40)$$

However, the numerical results in Gilbert and Nocedal [29] show that the Gilbert and Nocedal (GN) method is not as good as the PRP method, although it indeed performs better than the FR method.

The Polak–Ribière–Polyak Method

In 1969, Polak and Ribière [31] and Polyak [32] proposed another conjugate gradient parameter, independently, that is

$$\beta_k^{\text{PRP}} = \frac{g_k^T y_{k-1}}{\|g_{k-1}\|^2}, \quad (41)$$

where $y_{k-1} = g_k - g_{k-1}$. In practical computations, the PRP method performs much better than the FR method for many optimization problems because it can automatically recover once a small step is generated. For this, we still consider the exact line search. It follows from Equation (41) that

$$|\beta_{k+1}^{\text{PRP}}| \leq \|g_{k+1}\| \|g_{k+1} - g_k\| / \|g_k\|^2. \quad (42)$$

By using the relations (32), (33), and (42), we can obtain

$$\tan \theta_{k+1} \leq \sec \theta_k \|g_{k+1} - g_k\| / \|g_k\|. \quad (43)$$

Assume that the angle θ_k between $-g_k$ and d_k is close to $\frac{1}{2}\pi$ and $\|s_k\| = \|x_{k+1} - x_k\| \approx 0$. Then we have that $\|g_{k+1} - g_k\| \ll \|g_k\|$ and hence

$$\tan \theta_{k+1} \ll \sec \theta_k. \quad (44)$$

Consequently, the next search direction d_{k+1} will tend to $-g_{k+1}$ and avoid the occurrence of continuous tiny steps. The PRP method was believed to be one of the efficient conjugate gradient methods in the last century.

Nevertheless, the global convergence of the PRP method only proves for strictly convex functions [33]; for general functions, Powell [34] showed that the PRP method can cycle infinitely without approaching a solution even if the stepsize α_k is chosen to the least positive minimizer of the line search function. To change this unbalanced state, Gilbert and Nocedal [29] considered Powell [35]’s suggestion of modifying the PRP method by setting

$$\beta_k^{\text{PRP}^+} = \max\{\beta_k^{\text{PRP}}, 0\}, \quad (45)$$

and showed that this modification of the PRP method, called PRP^+ , is globally convergent both for exact and inexact line searches. More

exactly, Gilbert and Nocedal established the following result.

Theorem 3. *Suppose that Assumption 1 holds. Consider the PRP⁺ method, namely, Equations (2) and (3), where β_k is given by Equation (45). If the line search satisfies the standard Wolfe conditions (5) and (7), and the sufficient descent condition (10) for some constant $c > 0$, the method is globally convergent.*

The technique of their proof is quite sophisticated. First, they define the so-called Property (*), which is a mathematical lifting of the property of avoiding cycles of tiny steps.

Property (*). Consider the methods (2) and (3) and assume that $0 < \gamma < \|g_k\| \leq \bar{\gamma}$. Then we say that the method has Property (*), if there exist constants $b > 1$ and $\zeta > 0$ such that for all k ,

$$|\beta_k| \leq b, \quad (46)$$

and

$$\|s_{k-1}\| \leq \zeta \implies |\beta_k| \leq \frac{1}{2b}. \quad (47)$$

It is not difficult to see that both PRP and PRP⁺ possess such a property. Secondly, defining $u_k = d_k / \|d_k\|$, Gilbert and Nocedal observed that if $\beta_k \geq 0$ and if $\|d_k\| \rightarrow \infty$, u_k and u_{k-1} will tend to be the same, namely, $\|u_k - u_{k-1}\| \rightarrow 0$. Their proof then proceeds by contradiction. If there is no convergence, then $\|d_k\|$ must tend to infinity. Consequently, by Property (*), the method has to take big steps for at least half of the iterations, otherwise $\|d_k\|$ becomes finite. However, since d_k tends to be the same direction for sufficiently large k , the iterations will lie out of the bounded level set $\mathcal{L}$ if there are many big steps. A contradiction is then obtained.

The convergence result of Gilbert and Nocedal requires the sufficient descent condition (10). If the strong Wolfe line search is used instead of the standard Wolfe line

search, the sufficient descent condition can be relaxed to the descent condition of the search direction [22]. However, the following one-dimensional quadratic example shows that the PRP method with the strong Wolfe line search may generate an uphill search direction [36]. Consider

$$f(x) = \frac{1}{2} \lambda x^2, \quad x \in \mathbb{R}^1, \quad (48)$$

where $\lambda = \min\{1 + \sigma, 2 - 2\delta\}$ and suppose that the initial point is $x_1 = 1$. Then for any constant δ and σ satisfying $0 < \delta < \sigma < 1/2$, direct calculations show that the unit step-size satisfies the strong Wolfe conditions (5) and (6). Consequently, $x_2 = 1 - \lambda$ and

$$g_2^T d_2 = \lambda^2 (\lambda - 1)^3 > 0, \quad (49)$$

which means that d_2 is uphill. Thus, for any small $\sigma \in (0, 1)$, the strong Wolfe line search cannot guarantee the descent property of the PRP method even for convex quadratic functions.

To ensure the sufficient descent condition, required by Theorem 3 for the PRP⁺ method, in practical computations, Gilbert and Nocedal [29] designed a dynamic inexact line search strategy. As a matter of fact, their strategy applies to any of the methods (2) and (3) with nonnegative β_k 's. Let us look at Equation (9). If $g_k^T d_{k-1} \leq 0$, we already have Equation (10) since $\beta_k \geq 0$. On the other hand, If $g_k^T d_k > 0$, it must be the case that $g_k^T d_{k-1} > 0$, which means that a one-dimensional minimizer has been bracketed. Then $g_k^T d_{k-1}$ can be reduced and Equation (10) holds by applying a line search algorithm, such as that given by Lemaréchal [37], Fletcher [38], or Moré and Thuente [39]. Comparing with the PRP method, however, no significant improvement is reported in Gilbert and Nocedal [29] for the PRP⁺ method.

Is there any clever inexact line search that can guarantee the global convergence of the original PRP method? Grippo and Lucidi [15] answered this question positively by generalizing an Armijo-type line search in De Leone *et al.* [40]. Given constants $\tau > 0$, $\sigma \in (0, 1)$, $\delta > 0$, and $0 < c_1 < 1 < c_2$, their line search

aims to find

$$\alpha_k = \max \left\{ \sigma^j \frac{\tau |g_k^T d_k|}{\|d_k\|^2}; j = 0, 1, \dots, \right\} \quad (50)$$

such that $x_{k+1} = x_k + \alpha_k d_k$ and $d_{k+1} = -g_{k+1} + \beta_{k+1}^{\text{PRP}} d_k$ satisfy

$$f(x_{k+1}) \leq f(x_k) - \delta \alpha_k^2 \|d_k\|^2 \quad (51)$$

and

$$-c_2 \|g_{k+1}\|^2 \leq g_{k+1}^T d_{k+1} \leq -c_1 \|g_{k+1}\|^2, \quad (52)$$

Such a stepsize must exist because of the following observations. If α_k or, equivalently, $\|s_k\| = \|x_{k+1} - x_k\| = \alpha_k \|d_k\|$ is small, β_{k+1}^{PRP} tends to zero and hence d_{k+1} gets close to $-g_{k+1}$. On the other hand, the difference in the objective function, $f(x_{k+1}) - f(x_k)$, is $O(-g_k^T s_k)$ or $O(\|s_k\|)$, whereas the expected decrease is only of the second order $O(\|s_k\|^2)$. Therefore, Equations (51) and (52) must hold provided that α_k is sufficiently small. Furthermore, since the total reduction of the objective function is finite, the line search condition (51) enforces $\lim_{k \rightarrow \infty} \|s_k\| = 0$. By this property, the strong global convergence relation (14) can be achieved for the PRP algorithm of Grippo and Lucidi. From the view point of computations, Grippo and Lucidi [15] refined their line search algorithm so that the first one-dimensional minimizer of the line search function can be accepted. Again, the numerical experience [41] does not suggest a significant improvement of their algorithm over the PRP method.

Along the line of Grippo and Lucidi [15], Dai and Yuan [36] builds the strong convergence of the PRP method with constant stepsizes

$$\alpha_k \equiv \eta, \text{ where } \eta \in (0, \frac{1}{4L}) \text{ is constant,} \quad (53)$$

where L is the Lipschitz constant in Assumption 1. This result was extended in Dai [42] for the case that $\alpha_k \equiv \frac{1}{4L}$. Chen and Sun [43] further studied the PRP method together with

other conjugate gradient methods using fixed stepsizes of the form

$$\alpha_k = \frac{-\delta g_k^T d_k}{d_k^T Q_k d_k}, \quad (54)$$

where $\delta > 0$ is constant and $\{Q_k\}$ is a sequence of positive definite matrices determined in some way.

The Hestenes–Stiefel Method

In this section, we briefly discuss the HS conjugate gradient methods, namely, (2) and (3) where β_k is calculated by

$$\beta_k^{\text{HS}} = \frac{g_k^T y_{k-1}}{d_{k-1}^T y_{k-1}}. \quad (55)$$

Such a formula is first used by Hestenes and Stiefel in the proposition of the linear conjugate gradient method in 1952.

A remarkable property of the HS method is that, no matter whether the line search is exact or not, by multiplying Equation (3) with y_{k-1} and using Equation (55), we always have that

$$d_k^T y_{k-1} = 0. \quad (56)$$

In the quadratic case, y_{k-1} is parallel to Ad_{k-1} , where A is the Hessian of the function. Then Equation (56) implies $d_k^T Ad_{k-1} = 0$, that is, d_k is conjugate to d_{k-1} . For this reason, the relation (56) is often called *conjugacy condition*. If the line search is exact, we have by Equation (9) that $g_k^T d_k = -\|g_k\|^2$ since $g_k^T d_{k-1} = 0$. It follows that $d_{k-1}^T y_{k-1} = \|g_{k-1}\|^2$ and $\beta_k^{\text{HS}} = \beta_k^{\text{PRP}}$. Therefore the HS method is identical to the PRP method in the case of exact line searches. As a result, Powell [34]’s counterexample for the PRP method also applies to the HS method, showing the nonconvergence of the HS method with the exact line search. Unlike the PRP method, whose convergence can be guaranteed by the line search of Grippo and Lucidi [15], it is still not known whether there exists a clever line search such that the (unmodified) HS method is well defined at each iteration and converges globally. The answer is perhaps negative. One major observation is that, when $\|s_{k-1}\|$

is small, both the nominator and denominator of β_k^{HS} become small so that β_k^{HS} might be unbounded. Another observation is that, for any one-dimensional function, we always have

$$\begin{aligned} d_2 &= -g_2 + \beta_2^{\text{HS}} d_1 \\ &= -g_2 + \frac{g_2 \cdot y_1}{d_1 \cdot y_1} d_1 \\ &= -g_2 + g_2 = 0 \end{aligned} \quad (57)$$

independent of the line search. Consequently, there is some special difficulty to ensure the descent property of the HS method with inexact line searches.

Similar to the PRP⁺ method, we can consider the HS⁺ method, where

$$\beta_k^{\text{HS}+} = \max \left\{ \beta_k^{\text{HS}}, 0 \right\}. \quad (58)$$

In case of the sufficient descent condition (10), it is easy to verify that both HS and HS⁺ have Property (*). Further, we can similarly modify the standard Wolfe line search to ensure the sufficient descent condition and global convergence for the HS⁺ method. If the sufficient descent condition (10) is relaxed to the descent condition, Qi *et al.* [44] established the global convergence of a modified HS method, where β_k takes the form

$$\beta_k^{\text{QHL}} = \max \left\{ 0, \min \left\{ \beta_k^{\text{HS}}, \frac{1}{\|g_k\|} \right\} \right\}. \quad (59)$$

Early in 1977, Perry [45] observed that the search direction in the HS method can be written as

$$d_k = -P_k g_k, \quad (60)$$

where

$$P_k = I - \frac{d_{k-1} y_{k-1}^T}{d_{k-1}^T y_{k-1}}. \quad (61)$$

Noting that $P_k^T y_{k-1} = 0$, P_k is an affine transformation that transforms R^n into the null space of y_{k-1} . To ensure the descent property of d_k , however, we may wish the matrix P_k is positive definite. It is obvious that there is no positive definite matrix P_k such that $P_k^T y_{k-1} = 0$. Instead, we look for a positive

definite matrix P_k such that the conjugacy condition (56) holds. In case of exact line searches, it is sufficient to require P_k to satisfy

$$P_k^T y_{k-1} = s_{k-1}, \quad (62)$$

which is exactly the quasi-Newton equation (see Yuan [33] or the article on **Quasi-Newton Methods**). Following this line, we can consider to generate P_k by using the BFGS update from $y_{k-1} I$, where y_{k-1} is some scaling factor. This yields

$$\begin{aligned} P_k(y_{k-1}) &= y_{k-1} \left(I - \frac{s_{k-1} y_{k-1}^T + y_{k-1} s_{k-1}^T}{s_{k-1}^T y_{k-1}} \right) \\ &\quad + \left(1 + \frac{y_{k-1} \|y_{k-1}\|^2}{s_{k-1}^T y_{k-1}} \right) \frac{s_{k-1} s_{k-1}^T}{s_{k-1}^T y_{k-1}}. \end{aligned} \quad (63)$$

Shanno [46] explored this idea with $y_{k-1} = 1$ (namely, no scaling is considered in the BFGS update) and obtained the search direction

$$\begin{aligned} d_k &= -g_k + \left[\frac{g_k^T y_{k-1}}{s_{k-1}^T y_{k-1}} - \left(1 + \frac{\|y_{k-1}\|^2}{s_{k-1}^T y_{k-1}} \right) \right. \\ &\quad \left. \frac{s_{k-1} s_{k-1}^T}{s_{k-1}^T y_{k-1}} \right] s_{k-1} + \frac{s_{k-1} s_{k-1}^T}{s_{k-1}^T y_{k-1}} y_{k-1}. \end{aligned} \quad (64)$$

The methods (2) and (64) are called *memoryless BFGS methods* by Buckley [47]. It is easy to see that the memoryless BFGS method reduces to the HS method if the line search is exact. Without much more calculations and storage at each iteration, the memoryless BFGS method performs much better than the HS method in practical computations.

In case of inexact line searches, Dai and Liao [48] derived the following relation directly from Equations (60) and (62),

$$\begin{aligned} d_k^T y_{k-1} &= -(P_k g_k)^T y_{k-1} = -g_k^T (P_k^T y_{k-1}) \\ &= -g_k^T s_{k-1}. \end{aligned} \quad (65)$$

By introducing a scaling factor t , Dai and Liao considered a generalized conjugacy condition,

$$d_k^T y_{k-1} = -t g_k^T s_{k-1}, \quad (66)$$

and proposed the following choice for β_k ,

$$\beta_k^{\text{DL}}(t) = \frac{g_k^T y_{k-1} - t g_k^T s_{k-1}}{d_{k-1}^T y_{k-1}}. \quad (67)$$

Clearly, if the line search is exact, namely, $g_k^T s_{k-1} = 0$, the DL direction is identical to the HS direction. If $g_k^T s_{k-1} \neq 0$, an analysis for quadratic functions is presented in Dai and Liao [48], showing that for small values of t , the DL direction can bring a bigger descent in the objective function than the HS direction if an exact line search is done at the k th iteration. The numerical experiments in Dai and Liao [48] showed that the DL method with $t = 0.1$ is a significant improvement of the HS method. In addition, similar to PRP⁺ and HS⁺, Dai and Liao [48] established the global convergence of a modified DL method, where

$$\beta_k^{\text{DL}^+}(t) = \max \left\{ \frac{g_k^T y_{k-1}}{d_{k-1}^T y_{k-1}}, 0 \right\} - t \frac{g_k^T s_{k-1}}{d_{k-1}^T y_{k-1}}, \quad (68)$$

that allows negative values.

Two further developments of the DL method are made by Yabe and Takano [49] and Li *et al.* [50]. Specifically, based on a modified secant condition given by Zhang *et al.* [51,52], Yabe and Takano [49] suggested the variants of Equations (67) and (68) with the vector y_{k-1} replaced with

$$z_{k-1} = y_{k-1} + \left(\frac{\rho \lambda_k}{s_{k-1}^T u_{k-1}} \right) u_{k-1}, \quad (69)$$

where $\lambda_k = 6(f_{k-1} - f_k) + 3(g_{k-1} + g_k)^T s_{k-1}$, $\rho \geq 0$ is a constant, and $u_{k-1} \in R^n$ satisfies $s_{k-1}^T u_{k-1} \neq 0$ (for example, $u_{k-1} = d_{k-1}$). Li *et al.* [50] considered the modified secant condition in Wei *et al.* [53] and suggested the following replacement of y_{k-1} in Equations (67) and (68):

$$y_{k-1}^* = y_{k-1} + \frac{v_{k-1}}{\|s_{k-1}\|^2} s_{k-1}, \quad (70)$$

where $v_{k-1} = 2(f_{k-1} - f_k) + (g_{k-1} + g_k)^T s_{k-1}$. Owing to the use of precise modified secant conditions, certain numerical improvements are expected for these variants over the DL and DL⁺ methods.

DESCENT CONJUGATE GRADIENT METHODS

From the previous section, we can see that none of the FR, PRP, and HS methods can ensure the descent property of the search direction even if the strong Wolfe conditions (5) and (6) with arbitrary $\sigma \in (0, 1)$. For the FR method, the descent condition can be guaranteed by restricting $\sigma \leq 1/2$. However, this is not true any more for $\sigma > 1/2$. For any constant value of $\sigma \in (0, 1)$, there is always some possibility for the PRP and HS methods not to generate a descent search direction.

If a descent search direction is not produced, a practical remedy is to restart the method along $-g_k$. However, this might degrade the efficiency of the method since the second-derivative information achieved along the previous search direction is discarded [18]. From the previous section, we see that many efforts have been made for early conjugate gradient methods to guarantee a descent direction and hence avoid the use of the remedy, including modifying the conjugate gradient parameter β_k or designing some special line search. In this section, we will first address the conjugate descent method and then emphasize the Dai–Yuan method, both of which can ensure the descent condition under strong Wolfe conditions and standard Wolfe conditions, respectively. A hybrid of the two methods is briefly mentioned at the end, which can ensure a descent direction at every iteration without line searches.

The Conjugate Descent Method

In his monograph [38], Fletcher proposed the conjugate descent (CD) methods, namely, (2) and (3) with β_k given by

$$\beta_k^{\text{CD}} = \frac{\|g_k\|^2}{-d_{k-1}^T g_{k-1}}. \quad (71)$$

Other than the FR, PRP, and HS methods, the CD method can ensure the descent property of each search condition, provided that the strong Wolfe conditions (5) and (6) are used. To see this, we first introduce the

following variants of the strong Wolfe conditions, namely, (5) and

$$\sigma_1 g_k^T d_k \leq g(x_k + \alpha_k d_k)^T d_k \leq -\sigma_2 g_k^T d_k, \quad (72)$$

where $0 < \delta < \sigma_1 < 1$ and $0 \leq \sigma_2 < 1$. If $\sigma_1 = \sigma_2 = \sigma$, the above conditions reduce to the strong Wolfe conditions (5) and (6). Now, by Equations (9) and (71), we have

$$-g_k^T d_k = \|g_k\|^2 \left[1 + g_k^T d_{k-1} / g_{k-1}^T d_{k-1} \right]. \quad (73)$$

The above relation and Equation (72) indicate that

$$1 - \sigma_2 \leq -g_k^T d_k / \|g_k\|^2 \leq 1 + \sigma_1. \quad (74)$$

Since $\sigma_2 < 1$, the left inequality in Equation (74) means that Equation (10) holds with $c = 1 - \sigma_2$ and hence the descent condition holds.

Global convergence analysis of the CD method is made in Dai and Yuan [54] using the generalized strong Wolfe conditions (5) and (72). Specifically, if $\sigma_1 < 1$ and $\sigma_2 = 0$, it follows from Equations (71), (74) and (31) that

$$0 \leq \beta_k^{\text{CD}} \leq \beta_k^{\text{FR}}. \quad (75)$$

Therefore, by the result of Touati-Ahmed and Storey [30] related to the relation (37), there is global convergence of the CD method. However, for any $\sigma_2 > 0$, it is possible that the square norm $\|d_k\|^2$ in the method increases to infinity at an exponential rate. Specifically, Dai and Yuan [54] considered the following two-dimensional function

$$f(x, y) = \xi x^2 - y, \quad \text{where } \xi \in (1, 9/8), \quad (76)$$

and showed that the CD method with the generalized strong Wolfe line search may not solve Equation (76). In real computations, the CD method is even inferior to the FR method.

The Dai–Yuan Method

To enforce a descent direction in case of the standard Wolfe line search, Dai and

Yuan [12] proposed a new conjugate gradient method, where

$$\beta_k^{\text{DY}} = \frac{\|g_k\|^2}{d_{k-1}^T y_{k-1}}. \quad (77)$$

For the DY method, it follows by Equations (3), (77) and direct calculations that

$$g_k^T d_k = \frac{\|g_k\|^2}{d_{k-1}^T y_{k-1}} g_{k-1}^T d_{k-1}. \quad (78)$$

The fraction in Equation (78) is exactly the DY formula (77). With this observation, we can get an equivalent expression of β_k^{DY} from Equation (78),

$$\beta_k^{\text{DY}} = \frac{g_k^T d_k}{g_{k-1}^T d_{k-1}}. \quad (79)$$

The following theorem establishes the descent property and global convergence of the DY method with the standard Wolfe line search.

Theorem 4. *Suppose that Assumption 1 holds. Consider the DY methods, namely, (2) and (3) where β_k is given by Equation (77). If the line search satisfies the standard Wolfe conditions (5) and (7), we have that $g_k^T d_k < 0$ for all $k \geq 1$. Further, the method converges in the sense that $\liminf_{k \rightarrow \infty} \|g_k\| = 0$.*

Proof. It is obvious that $d_1^T g_1 < 0$ since $d_1 = -g_1$. Assume that $g_{k-1}^T d_{k-1} < 0$. It follows by this and Equation (7) that $d_{k-1}^T y_{k-1} > 0$. Thus by Equation (78), we also have that $g_k^T d_k < 0$. Therefore by induction, $g_k^T d_k < 0$ for all $k \geq 1$.

Now, let us denote

$$q_k = \frac{\|d_k\|^2}{(g_k^T d_k)^2}, \quad r_k = -\frac{g_k^T d_k}{\|g_k\|^2}. \quad (80)$$

Dividing Equation (15) by $(g_k^T d_k)^2$ and using Equations (79) and (80), we obtain

$$q_k = q_{k-1} + \frac{1}{\|g_k\|^2} \frac{2}{r_k} - \frac{1}{\|g_k\|^2} \frac{1}{r_k^2}. \quad (81)$$

Noting that $\frac{2}{r_k} - \frac{1}{r_k^2} \leq 1$, an immediate corollary of Equation (81) is

$$q_k \leq q_{k-1} + \|g_k\|^{-2}. \quad (82)$$

Assume that $\liminf_{k \rightarrow \infty} \|g_k\| \neq 0$ and Equation (19) holds. By Equations (19), (82) and $d_1 = -g_1$, we have $q_k \leq k/\gamma^2$ and hence $\sum_{k \geq 1} q_k^{-1} = +\infty$, which contradicts the Zoutendijk condition (12). Therefore the statement is true.

By Equation (81), we can further exploit the self-adjusting property of the DY method [55]. To this aim, we first notice that the r_k defined in Equation (80) is a quantity that reflects the descent degree of the search direction d_k , since the descent condition (8) is equivalent to $r_k > 0$ and the sufficient condition (10) is the same as $r_k \geq c$. Now let us focus on the relation (81). The second term on the right side of Equation (81) increases the value of q_{k-1} , whereas the third term decreases the value of q_{k-1} . Considering the two terms together, we see that q_{k-1} increases if and only if $r_k \geq 1/2$. If r_k is close to zero, then q_{k-1} will be significantly reduced, since the order of $1/r_k$ in the second term is only one, but its order in the third term is two. This and the fact that $q_k \geq 0$ for all k imply that, in the case when q_{k-1} is very small, r_k must be relatively large. Further investigations along the observations can lead to the following result of the DY method independent of the line search.

Theorem 5. *Consider the DY methods (2),(3) and (77), where d_k is a descent direction. Assume that $0 < \gamma \leq \|g_k\| \leq \bar{\gamma}$ holds for all $k \geq 1$. There must exist positive constants δ_1, δ_2 and δ_3 such that the relations*

$$-g_k^T d_k \geq \frac{\delta_1}{\sqrt{k}}, \quad \|d_k\|^2 \geq \frac{\delta_2}{k}, \quad r_k \geq \frac{\delta_3}{\sqrt{k}} \quad (83)$$

hold for all $k \geq 1$. Further, for any $p \in (0, 1)$, there must positive constants $\delta_4, \delta_5, \delta_6$ such that, for any k , the relations

$$-g_i^T d_i \geq \delta_4, \quad \|d_i\|^2 \geq \delta_5, \quad r_i \geq \delta_6 \quad (84)$$

holds for at least $[pk]$ values of $i \in [1, k]$.

The above theorem enables us to establish global convergence for the DY method provided that the line search is such that

$$f_k - f_{k+1} \geq c \min \left\{ -g_k^T d_k, \|d_k\|^2, q_k^{-1} \right\}, \quad (85)$$

for all $k \geq 1$ and some $c > 0$. Consequently, we can analyze the convergence properties of the DY method using the standard Wolfe line search, the Armijo line search [56], and the line search proposed in De Leone *et al.* [40] and Grippo *et al.* [57] for no-derivative methods.

In general, once some optimization method fails to generate a descent direction, a usual remedy is to do a restart along $-g_k$. As shown in Dai [55], the DY direction can act the role of the negative gradient and meanwhile guarantee the global convergence. A numerical experiment with the memoryless BFGS method in Dai [55] demonstrated this finding.

Since the DY method has the same drawback as the FR method, namely, it cannot recover from cycles of tiny steps, it is natural to consider the hybrid of the DY and HS methods like those for the FR and PRP methods in Touati-Ahmed and Storey [30] and Gilbert and Nocedal [29]. Under the standard Wolfe line search, Dai and Yuan [13] extended Theorem 4 to any method (2),(3) with

$$\beta_k \in \left[-\frac{1-\sigma}{1+\sigma} \beta_k^{\text{DY}}, \beta_k^{\text{DY}} \right], \quad (86)$$

where σ is the parameter in the Wolfe condition (7). In spite of a large admissible interval, the numerical results of Dai and Yuan [13] indicated that the following hybrid is preferable in real computations

$$\beta_k^{\text{DYHS}} = \max \left\{ 0, \min \left\{ \beta_k^{\text{HS}}, \beta_k^{\text{DY}} \right\} \right\}. \quad (87)$$

Unlike the Touati-Ahmed and Storey (TS) and GN hybrid methods, the DYHS method using standard Wolfe line searches performs much better than the PRP method using

strong Wolfe line searches [13]. The latter was generally believed to be one of the most efficient conjugate gradient algorithms.

It is well known that some quasi-Newton methods can be expressed in a unified way and their properties can be analyzed uniformly [58,59]. On the contrary, nonlinear conjugate gradient methods were often analyzed individually. To change the situation, Dai and Yuan [60] proposed a family of conjugate gradient methods, in which

$$\begin{aligned} \beta_k(\lambda) &= \frac{\|g_k\|^2}{\lambda\|g_{k-1}\|^2 + (1-\lambda)d_{k-1}^T y_{k-1}}, \quad \lambda \in [0, 1]. \end{aligned} \quad (88)$$

This family can be regarded as some kind of convex combination of the FR and DY methods. Dai and Yuan [61] further extended the family to the case $\lambda \in (-\infty, +\infty)$ and presented some unified convergence results. Independently, Nazareth [8] regarded the FR, PRP, HS, and DY formulas as the four leading contenders for the conjugate gradient parameter and proposed a two-parameter family:

$$\begin{aligned} \beta_k(\lambda_k, \mu_k) &= \frac{\lambda_k\|g_k\|^2 + (1-\lambda_k)g_k^T y_{k-1}}{\mu_k\|g_{k-1}\|^2 + (1-\mu_k)d_{k-1}^T y_{k-1}}, \\ \lambda_k, \mu_k &\in [0, 1]. \end{aligned} \quad (89)$$

The methods that take the convex combination $\lambda_k\beta_k^{\text{HS}} + (1-\lambda_k)\beta_k^{\text{DY}}$, considered in Andrei [62], can be regarded as a subfamily of Equation (89) with $\mu_k = 0$. Several efficient choices for λ_k in this subfamily are also studied in Andrei [62] based on different secant conditions.

Later, based on FR, PRP, HS, DY, CD, and the formula

$$\rho_k^{\text{LS}} = \frac{g_k^T y_{k-1}}{-d_{k-1}^T g_{k-1}} \quad (90)$$

by Liu and Storey [63], Dai and Yuan [64] proposed a three-parameter family

$$\begin{aligned} \beta_k(\lambda_k, \mu_k, \omega_k) &= \frac{\|g_k\|^2 - \lambda_k g_k^T g_{k-1}}{\|g_{k-1}\|^2 + \mu_k g_k^T d_{k-1} - \omega_k \beta_{k-1} g_{k-1}^T d_{k-2}}, \end{aligned} \quad (91)$$

where $\lambda_k \in [0, 1]$, $\mu_k \in [0, 1]$, and $\omega_k \in [0, 1 - \mu_k]$ are parameters. One subfamily of the methods (91) with $\lambda_k = 1$, $\mu_k = 0$, and $\omega_k = u$ is studied in Shi and Guo [65] with an efficient nonmonotone line search. Further, Dai [66] studied a family of hybrid conjugate gradient methods, in which

$$\begin{aligned} \beta_k(\mu_k, \omega_k, \tau_k) &= \frac{\max\{0, \min\{g_k^T y_{k-1}, \tau_k \|g_k\|^2\}\}}{(\tau_k + \omega_k)g_k^T d_{k-1} + \mu_k \|g_{k-1}\|^2 + (1-\mu_k)(-d_{k-1}^T g_{k-1})}, \end{aligned} \quad (92)$$

where $\mu_k \in [0, 1]$, $\omega_k \in [0, 1 - \mu_k]$ and $\tau_k \in [1, +\infty)$ are parameters.

The DYCD Method

Suppose that M is some fixed positive integer, and λ and δ are constants in $(0, 1)$. Given an initial guess $\bar{\alpha}_k$ at the k th iteration, the nonmonotone line search by Grippo *et al.* [67] is to compute the least nonnegative integer m such that the steplength $\alpha_k = \bar{\alpha}_k \lambda^m$ satisfies the following relation:

$$f(x_k + \alpha_k d_k) \leq \max\{f_k, \dots, f_{k-M(k)}\} + \delta \alpha_k g_k^T d_k, \quad (93)$$

where $M(k) = \min(M, k-1)$. To enforce a descent search direction at every iteration in this situation, Dai [14] considered a hybrid of the DY and CD methods, namely, (2) and (3) with

$$\beta_k^{\text{DYCD}} = \frac{\|g_k\|^2}{\max\{d_{k-1}^T y_{k-1}, -d_{k-1}^T g_{k-1}\}}. \quad (94)$$

It is proved in Dai [14] that the DYCD method possesses the descent property without line searches. Further, there is the global convergence if the DYCD method is combined with
